INFORMATION TO USERS

This manuscript has been reproduced from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

The quality of this reproduction is dependent upon the quality of the copy submitted. Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps.

ABSTRACT

Thermochronology and Geobarometry of the Granite Mountains, southeast California; Exhumation of a plutonic complex during collapse of the Sevier Orogen

by

Joseph L. Kula

Dr. Terry L. Spell, Examination Committee Chair
Associate Professor of Geology
University of Nevada, Las Vegas

Thermochronologic data and geobarometry from the Granite Mountains indicate exhumation of mid-crustal plutons during Late Cretaceous extensional tectonics. U/Pb zircon and $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende ages indicate intrusion, crystallization, and geologically instantaneous cooling through 500 °C at ~75 Ma. K-feldspar multi-diffusion domain modeling indicates a cooling rate gradient from SW to NE of 63, 32, and 16 °C/Ma for three samples spanning a transect across the range. NE K-feldspar cooled through ~252 °C by 73 Ma while other samples remained >375 °C suggesting a short lived down-to-the-east normal faulting event at ~75 to 74 Ma. Faster cooling rates with later initial K-feldspar recording (~71 Ma) suggest extension continued along a shallow down-to-the-southwest detachment active from ~73 to 69 Ma. U-Th/He apatite ages suggest the Late Cretaceous extensional event juxtaposed the deeper-seated Granite Mountains plutons with the shallow-level southern Providence Mountains plutons and the two cooled through 70 °C as a single block.

ACKNOWLEDGEMENTS

So many people unselfishly put time towards this project that it would be criminal for me to accept credit for its completion without acknowledging them and expressing my gratitude. On the reverse side of that coin, it would also be unfair for me to take all the blame without revealing all co-conspirators and guilty parties, so here it goes.

My advisor, Teespell, has been patient beyond the bounds of most human forms and I thank him graciously for it. For over two years he has been an incredible mentor and friend even after sitting through my psychotic ramblings and falling victim to my constant acts of immaturity.

I will never understand how one person can remember so much geology and come up with so many difficult questions, but I have to thank Michael Wells for doing it. I have benefited greatly from having him serve on my committee and I appreciate all of the conversations we have had. I would also like to thank Rod Metcalf for being on my committee and offering constructive criticism, a relaxed presence during consultation, and insight on barometry work, not to mention 'giving me shi, err...crap.' Barbara Luke is thanked for serving on my committee as well as for being easily approachable and genuinely professional and kind.

Keith A. Howard at the U.S.G.S. Menlo Park, CA is thanked for supplying unpublished K-Ar dates from the Granite Mountains and insight throughout this project. Ken A. Farley at California Institute of Technology is thanked for allowing me to visit his laboratory and for running U-Th/He apatite analyses. I would like to thank Oscar Lovera

at UCLA for his patience with my infinite number of questions regarding his computer programs.

I am very grateful for conversations about my thesis project with Andrew Hanson, Cathy Snelson, and Wanda Taylor. A gargantuan thank you is in order for Kathy Zanetti for letting me hang out in the lab all the time, helping me with my $^{40}\text{Ar}/^{39}\text{Ar}$ age determinations, putting up with my ridiculous antics, and getting me thrown out of “The Beach.”

I thank my family for their long distance support, and advice in the kitchen. I am grateful to Pabst for offering a vegan beer at an inexpensive cost. Also, I need to thank my friends who have given me mental support even when they didn’t realize they did it. I believe they know who they are (and do not need to see their name in a list here) and I thank these friends for being approachable, fun, and ‘there’ by choice and not obligation. An extra special ‘thank you’ goes to Melissa for just being. Of course, I also thank the Geoscience Department at UNLV for supporting me and allowing me to continue my graduate education here. I’m having a lot of fun.

This project was funded by UNLV SITE Grants, UNLV GSA Research Grants, UNLV Geoscience Department Research Grants, and Arizona-Nevada Academy of Science Research Grants.

CHAPTER 1

INTRODUCTION

In some areas of the North American Cordilleran interior evidence for rapid exhumation of mid-crustal rocks during the late Cretaceous extensional collapse of the Sevier Orogen is well documented (Foster et al., 1989; Wells et al., 1990; Hodges and Walker, 1992; Miller et al., 1996). However, in many areas this event is neither confirmed nor dated, partly because mid-Cenozoic extension (Basin and Range tectonics) also took place in the region (Foster et al., 1990). This results in a lack of evidence for north-south continuity of late Cretaceous extensional structures. This study focuses on the Granite Mountains, located in the eastern Mojave Desert of California. The Granite Mountains are situated at the southernmost extent of the Sevier Orogenic belt, an area in which details of the Sevier Orogeny are incompletely understood (Fig. 1).

Purpose

The Granite Mountains are a mid to deep-crustal plutonic complex consisting of Mesozoic granitoids that are also exposed to the northeast in the southern Providence Mountains (Howard et al., 1987; Young and Wooden, 1988; Fox and Miller, 1990). Previous geochronology in the Granite Mountains indicates preservation of Mesozoic isotopic signatures, suggesting the cooling histories of plutons may record Late Cretaceous exhumation and not Tertiary tectonic overprinting (Basin and Range

Figure 1. Mesozoic Sevier thrust belt and Cenozoic Basin and Range Province (gray). Modified from Lageson and Schmitt (1994) and Burchfiel et al. (1992). Square represents study area.

Extension). The purpose of this research project is to further document Late Cretaceous extensional tectonics at the southern extremity of the Sevier Orogen by using isotopic dating techniques and geobarometry to document the intrusion and exhumation history of Granite Mountains plutons. Timing of exhumation for these plutons may then be related to the known tectonic events that have affected the region, which include extensional collapse of the Sevier Orogen (Mesozoic) and Basin and Range Extension (Miocene).

Significance of Study

Contraction and subsequent extension in the Sevier Orogen were significant events in the geologic history of western North American. Although the Sevier Orogeny has been intensively studied for decades, its tectonic history remains incomplete. In Death Valley, the Mojave Desert, and adjacent terrains of the southern Sevier region, understanding of the tectonic history is limited due to both insufficient geochronological data and overprinting by Basin and Range extension. The results of this project provide information on the timing and rates of Late Cretaceous Sevier extensional tectonics. Information gained from this study not only adds to the growing body of knowledge of the geologic evolution of the North American continent, but also may be applicable to presently active orogens (e.g. Himalayan Mountains). A more complete understanding of the timing and regional extent of past orogenic events may allow for better interpretation and perhaps prediction of the tectonics of active orogenic terrains.

Research Questions / Hypothesis

The hypothesis for this study is that the exhumation of Granite Mountains plutons was a result of Late Cretaceous extensional collapse of the Sevier orogeny. Questions formulated to test the hypothesis and meet project goals include (1) What were the timing and rates of exhumation? and (2) What known tectonic event(s) led to the exhumation of plutons of the Granite Mountains?

The main goals of this project are (1) to determine the depth and timing of emplacement for plutons in the Granite Mountains, (2) construct the subsequent cooling histories for these plutons, and (3) relate these results to known tectonic events that have affected the region.

Field relations of rock units along with previous investigations in the Granite-Providence Mountains region suggests that these ranges may represent parts of a continuous crustal section. Exposures of shallow-to-mid-crustal rocks in the southern Providence Mountains have been described as similar to the mid-to-deep-crustal rocks found in the northern Granite Mountains (Miller et al., 1985; Young and Wooden, 1988; Young et al., 1992). This may be a preliminary indication that the Granite and southern Providence Mountains represent a tilted crustal section, or perhaps a crustal section with its deeper and shallower sections juxtaposed at the surface following extensional tectonics. This possibility may be resolved by answering several secondary research questions. These questions include (1) Is this an intact crustal section? If so (2) did tilting during exhumation expose deep plutons of the Granite Mountains adjacent to shallower plutons of the Southern Providence Mountains, or was some other process responsible?, and (3) What is the structural/ tectonic link between these two mountain ranges?

Figure 2. Geologic map of Granite Mountains and southern Providence Mountains in the east Mojave Desert, California (from Miller et al., 1985; Miller et al., 1991). Black circles indicate locations sampled. Arrows pointing to open circles indicate sample locations for Calvin from monzogranite pluton, Floyd from a central granodiorite pluton, Yoshi from a northeast quartz monzonite pluton, and Omar from the syenogranite of Quail Spring in the southern Providence Mountains. Along the northern base of the range is the Bull Canyon Fault. Fault lines in the eastern Providence Mountains represent the East Providence Fault Zone. Dotted line southwest of the Granite Mountains indicates inferred location of the Bristol-Granite Mountains fault zone. The fault through Granite Pass lies between Cretaceous rocks in the Granite Mountains and Jurassic rocks in the southern Providence Mountains.

Figure 2. Southern Providence Mts.

CHAPTER 2

REGIONAL GEOLOGY

Sevier Orogeny

The Sevier Orogen is defined by a series of contractional structures extending north-south through western North America (Armstrong, 1968) (Fig. 1). Together, these structures are referred to as the Sevier fold-thrust belt. Deformation and plutonism of the Sevier Orogeny began in the Late Jurassic due to Farallon-North American plate convergence (Burchfiel et al., 1992). An increasing rate in Farallon plate subduction resulted in intensified arc magmatism, which heated and weakened overlying crust allowing fold-thrust deformation. By about early Cretaceous time a continuous belt of east-vergent thrust faults stretched from Canada to southeastern California (Livaccari, 1991; Burchfiel et al., 1992). To the west of this fold and thrust belt are associated Late Jurassic plutons (~165 to 140 Ma) that cut earlier Mesozoic deformational fabrics, folds, and thrust faults (Walker et al., 1995a; Burchfiel et al., 1992). The Sevier belt may be entirely younger than these plutons since the time of initial thrust faulting of the Sevier belt is unclear (Burchfiel et al., 1992). Evidence has been presented indicating development of east-vergent allochthons in the latest Jurassic to early Cretaceous (Armstrong and Oriel, 1965), whereas Heller et al. (1986) suggest the beginning of Sevier thrust faulting at about early Cretaceous time.

Overthickening of the continental crust resulting from convergent tectonics of the Sevier Orogen led to extensional collapse in the Late Cretaceous (Foster et al., 1989; Wells and Allmendinger, 1990; Wells, 1997). Extension in the Sevier hinterland has been well documented in Utah (Wells et al., 1990; Wells, 1997) and parts of California (Foster et al., 1989; Applegate et al., 1992; Miller et al., 1996). However, Mesozoic extensional structures and isotopic signatures related to the Sevier Orogeny are discontinuous due to subsequent overprinting by Cenozoic Basin and Range tectonics (Fig. 1).

Southeast California

Basement rocks of the eastern Mojave Desert are granitoids and high-grade gneisses and schists that were deformed and accreted to the North American craton in the Early Proterozoic (Bennett and Depaolo, 1987; Wooden et al., 1988). Middle Proterozoic anorogenic granitoids and diabases later intruded these rocks (Anderson, 1983; Fitzgibbon and Howard, 1987). During episodes of marine transgression and regression, the region was covered by 1-2 km of carbonate dominated sedimentary rocks during the Paleozoic and early Mesozoic (Stone et al., 1983). Deformation, plutonism and metamorphism during the Middle Jurassic occurred in the western and central Mojave Desert with tectonism also documented to the east in the Marble, Ship, Clipper, Piute, and Old Woman Mountains during the Late Jurassic to Cretaceous (Bishop, 1964; DeWitt et al., 1984; Burchfiel and Davis, 1981; Foster et al., 1990; Howard et al., 1995) (Fig. 3).

Figure 3. Map showing several locations in the Sevier hinterland that record extension during the Late Cretaceous gravitational collapse of the Sevier Orogen. FM=Funeral Mountains; RR=Raft River Mountains; NM=New-foundland Mountains; BP=Black Pine Mountains; NYM=New York Mountains; PM=Providence Mountains; OW/P=Old Woman-Piute Mountains; GM=Granite Mountains (study area). Also shown are the Clipper Mountains (CM), Ship Mountains (SM), and Marble Mountains (MM). Adapted from Applegate et al. (1992), Allmendinger and Jordan (1984), Beyene et al., (2000), Miller et al., (1996), Foster et al., (1992), Wells et al. (1990), and Wells (1997).

Jurassic and Cretaceous age plutons in the Mojave Desert are part of larger magmatic arcs that extend throughout the U.S. Cordillera (Fox and Miller, 1992) (Fig. 4). In the Mojave region, Cretaceous plutonic rocks have compositions ranging from granodiorite to monzogranite, and are compositionally more homogeneous than Jurassic plutonic rocks (Fox and Miller, 1992). Jurassic intrusive rocks are more compositionally diverse and K₂O-rich and mainly yield K/Ar and U/Pb ages of 160 to 150 Ma and 165 to 160 Ma, respectively (Fox and Miller, 1992), although Latest Jurassic (~145 Ma) plutons have been dated north of the Granite Mountains in the Clark Mountains, Mescal Range, Striped Mountain, and Ivanpah Mountains. Cretaceous plutonic rocks are exposed as large composite batholiths throughout the region (Fox and Miller, 1990). These include the Teutonia batholith (Beckerman et al., 1982; Fox and Miller, 1990), the Cadiz valley batholith (John, 1981; Fox and Miller, 1990), and the Old Woman-Piute batholith (Foster et al., 1990). Cretaceous plutons were emplaced during two intervals based on U-Pb zircon geochronology; 99 to 95 Ma and 75 to 70 Ma (Wright et al., 1987; Fox and Miller, 1992).

Granite Mountains

The Granite Mountains expose rocks ranging in age from Paleozoic to Cenozoic, but are dominated by Mesozoic plutonic rocks described above (Howard et al., 1987) (Fig. 2). Metasedimentary rocks are exposed at higher elevations as small roof pendants (Howard et al., 1987). These metamorphosed strata are dominantly marble and siliceous marble, which may correlate lithologically with the Bird Spring Formation (Pennsylvanian and Permian) and the Monte Cristo Limestone (Mississippian) that are exposed in the northern Providence Mountains to the northeast (Howard et al., 1987).

Figure 4. Map of Mesozoic magmatic arcs extending through the southern U.S. Cordillera (after Fox and Miller, 1990). Rectangle indicates area of study in the Mojave Desert.

Previous U/Pb and K/Ar ages from the Granite Mountains (Chapter 3) indicate preservation of original Mesozoic isotopic signatures and thus potential to provide information about Late Cretaceous tectonics. Previous geobarometry (Chapter 3) in the Granite Mountains region, indicating mid-to-deep crustal emplacement for Granite Mountains plutons and shallow crustal emplacement for southern Providence Mountains plutons, may have implications for a structural relationship between the Granite and southern Providence Mountains.

In contrast with the heavily faulted Old Dad Mountains to the west, there are few faults in the interior of the Granite Mountains; however, several faults are present on the perimeter (Howard et al., 1987) (Fig. 2). The Bull Canyon fault, a late Tertiary low-angle normal fault, traces around the northern margin of the Granite Mountains (Howard et al., 1987). The fault dips outward from the range at 20-40° north and northwest, and exposes a zone of red to tan breccia and gouge separating a chloritically altered footwall of Jurassic plutonic rocks from a hanging wall of chloritized and brecciated equivalents and Tertiary sedimentary breccia (Howard et al., 1987). Separating the Granite Mountains from the Old Dad Mountains is the northwest-striking Bristol-Granite Mountains fault zone (Gamble, 1959a,b; Howard et al., 1987; Howard and Miller, 1992) (Fig. 2). This fault dips northeast 70-80° and places Mesozoic plutonic rocks in the northeast over Tertiary supracrustal rocks in the southwest, indicating reverse motion (Howard et al., 1987). This fault has been described as a potential southern continuation of dextral-strike-slip faults in Death Valley, (Hamilton and Myers, 1966; Brady, 1988) and the eastern limit of the eastern California shear zone (Howard and Miller, 1992; Dokka and Travis, 1990) while Davis et al. (1974) suggest that the Bristol-Granite Mountains fault

zone is older than the southern Death Valley fault zone. In the northeast, a normal fault extends at least 3 km long striking northwest and dipping 45-50° to the northeast (Howard et al., 1987) (Fig. 2). A north-northwest striking fault to the east in Granite Pass places Cretaceous granite of the Granite Mountains against Jurassic syenogranite in the southern Providence Mountains (Howard and Miller, 1992) (Fig.2). This fault is interpreted as a down-to-the-east normal fault by Howard and Miller (1992), based on a greater abundance and coarser grain size of the Cretaceous granite west of the fault compared to that exposed to the east.

Providence Mountains

The Providence Mountains lie to the northeast of the Granite Mountains (Fig. 2). The southern region of these mountains consists of Mesozoic granitic plutons similar to those exposed in the Granite Mountains. Young and Wooden (1988) determined mid-to shallow crustal emplacement depths for these plutons using aluminum-in-hornblende geobarometry (Chapter 3). Along the east side of this range is the East Providence fault zone (Fig. 2), consisting of several steeply dipping (~65°-75°) down-to-the-west normal faults (Miller et al., 1996). The East Providence fault zone has been correlated as a segment of the East Mojave fault, which is a ~70 km long north-to northwest-striking Cretaceous extensional structure spanning across the eastern Mojave Desert (Miller et al., 1996).

CHAPTER 3

PREVIOUS WORK

Granite and southern Providence Mountains

Previous geochronology has yielded U/Pb zircon ages of ~174 Ma for a large Jurassic hornblende-quartz diorite (unit Jqd, Fig. 2) in the west-central region of the Granite Mountains (Howard, 2000) and 155 Ma for an adjacent diorite pluton (unit Jd, Fig. 2) (Young et al., 1992). A pluton described by Miller et al. (1991) as Cretaceous porphyritic monzogranite (unit Kpm, Fig. 2) gave a U/Pb zircon age of ~70 Ma and a K/Ar biotite age of 70.9 Ma (Howard, 2000). Other data include K/Ar ages for hornblendes and biotites ranging from 64 to 74 Ma (Miller et al., 1991; Howard, 2000). These ages indicate preservation of original Mesozoic isotopic signatures and thus potential to provide information about Late Cretaceous tectonics.

Aluminum-in-hornblende geobarometry indicates crystallization pressures of 6.0 to 7.5 kbar for Jurassic and Cretaceous granitoids in the northern Granite Mountains, corresponding to emplacement depths of 19 to 25 km (Young and Wooden, 1988). Lower crystallization pressures of ~3 kbar suggest mid to shallow crustal emplacement at 8-16 km depth for plutons exposed at the southern extent of the Providence Mountains (Fox and Miller, 1990; Young and Wooden, 1988) (Fig. 2). This may indicate exposure of deeper and shallower segments of a single crustal section.

Mojave Desert Region

The Granite Mountains belong to a region of the East Mojave Desert that records substantial contractional and extensional tectonics as well as plutonism in the Jurassic, Cretaceous and Miocene (Howard et al., 1995). Late Cretaceous extension is recorded in the East Providence fault zone along the east side of the Providence Mountains (Fig. 2) as well as in the Piute and Old Woman Mountains, ~65 km to the southeast (Foster et al. 1990), the Funeral Mountains in Death Valley (Applegate et al., 1992), and the New York Mountains, ~60 km northeast of the Granite Mountains (Beyene, 2000) (Fig. 3). The Old Woman Mountains underwent rapid unroofing and denudation at the end of the Cretaceous (~73-70 Ma), probably accommodated by a top-to-the-southwest shear zone (Foster et al., 1992; Carl et al., 1991; Gerber et al., 1995). Unroofing of the Funeral Mountains metamorphic core complex has been constrained by U/Pb zircon geochronology between 72 and 70 Ma (Applegate et al., 1992) (Fig. 3). Late Cretaceous extension (>70-65 Ma) was documented in the Pinto Shear Zone in the New York Mountains (Beyene, 2000) (Fig. 3). The Pinto shear zone is a top-to-the-southwest normal-sense shear zone active from ~71 to 65 Ma, based on $^{40}\text{Ar}/^{39}\text{Ar}$ thermochronology of K-feldspar, biotite, and muscovite (Beyene et al., 2000). Together, the Pinto, East Providence, and Cima (also a down to the southwest normal shear zone) fault zones make up the East Mojave fault, which shows evidence for widespread down to the southwest Late Cretaceous extension stretching from the Old Woman Mountains to the south, north to the Funeral Mountains in the Death Valley region.

Further north, extension in the hinterland of the Sevier belt is recorded in the Newfoundland Mountains, Utah, (Allmendinger and Jordan, 1984) the Black Pine

Mountains, Idaho, (Wells et al., 1990) and the Raft River Mountains, Utah (Wells et al., 1990; Wells, 1997; Wells et al., 1998) (Fig. 3). Mesozoic normal faults in the Newfoundland Mountains suggest extension following Sevier shortening (Allmendinger and Jordan, 1984). $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology on synkinematically-metamorphosed rocks from the Raft River and Black Pine Mountains suggests east-west extension in the Sevier hinterland occurred during the Late Cretaceous (Wells et al., 1990). These data support the idea of widespread extensional collapse of the Sevier orogenic belt as a result of crustal overthickening during earlier (Jurassic-Cretaceous) contractional tectonics (Hodges and Walker, 1992; Livaccari, 1991).

CHAPTER 4

SAMPLING STRATEGY AND ANALYTICAL METHODS

Sample Collection

Approximately 40 samples were collected across the Granite Mountains into the southern Providence Mountains. Four samples; Omar, Yoshi, Calvin, and Floyd (appendix a), were selected for analyses based on the criteria that they (1) contain the appropriate mineral assemblages for isotopic dating techniques and geobarometry, (2) were representative of their host pluton, and (3) formed a transect across the Granite Mountains into the southern Providence Mountains. Calvin, Floyd, and Yoshi, from the Granite Mountains, represent mapped units of monzogranite (Kpm), granodiorite (Kgd), and quartz monzonite (Jsq/Ksq), respectively, of Miller et al. (1991) (Fig. 2). Omar was collected from syenogranite (Jgo) in the Providence Mountains (Fig. 2). Throughout this thesis, plutons will be referred to by the map unit names of Miller et al. (1991), whereas corresponding sample names are quoted in the appendices.

Mineral Separation/Preparation Techniques

Prior to mineral separation, rock samples were crushed and sieved. Separation of zircon, hornblende, and K-feldspar was done using heavy liquids. Methylene iodide (SG = 3.32) was diluted with acetone to SG = ~2.60 to separate K-feldspar from quartz and

plagioclase. Franz isodynamic magnetic separators, and hand picking were used in the final stages of purification. Zircon was extracted from the 50 – 150 μm fraction. Hornblende and K- feldspar separates, purity >99%, were taken from 150 – 250 μm fractions.

Apatite separations were done by Donelick Analytical, Inc. Samples were crushed and sieved below 300 μm mesh and separated using SG = 3.0 lithium metatungstate, SG = 3.3 diiodomethane, and a Franz magnetic separator. Apatites were divided into two size fractions, >106 μm and <106 μm of which the former was used for final selection of crystals for analysis.

Aluminum-in-hornblende Geobarometry

Hornblende is a common phase in hydrous calc-alkalic magmas crystallizing at depth. The composition of hornblende has been found to vary with rock composition, pressure, and temperature (Hammerstrom and Zen, 1986; Hollister et al., 1987). Using electron microprobe analyses on hornblende from rocks with independently known pressures of crystallization, Hammarstrom and Zen (1986) presented an initial empirical correlation between the total Al (Al_T : total number of cations of Al per formula unit based on 23 oxygens) in hornblende and the estimated pressure of crystallization for calc-alkaline granitoid rocks with the mineral assemblage plagioclase + K-feldspar + quartz + hornblende + biotite + sphene + magnetite. This is now referred to as the aluminum-in-hornblende geobarometer (Hammerstrom and Zen, 1986). Pressure estimates were made on plutons crystallizing at shallow and deep crustal levels (1.5-3 kbar and 7-10 kbar) resulting in a calibration with ± 3 kbar uncertainties.

Hollister et al. (1987) subsequently confirmed and refined the correlation by independently determining pressures for plutons crystallizing at mid-crustal depths (4–6 kbar), thus filling the gap in the Hammarstrom and Zen (1986) data. The results of Hollister et al. (1987) included a reduction in error to ± 1 kbar. A number of studies have subsequently refined the aluminum-in-hornblende geobarometer. These include Johnson and Rutherford (1989), Rutter et al. (1989), Schmidt (1992), Anderson and Smith (1995), and Ague (1997). All of these calibrations yield slightly different pressure estimates although they essentially overlap within uncertainties.

Analyses for aluminum-in-hornblende geobarometry were done at the Electron Microanalysis and Imaging Laboratory at UNLV using a JEOL 8900 Electron Probe Microanalyzer. Instrument parameters were a $1\mu\text{m}$ spot size with a 2×10^{-8} A beam intensity and an accelerating voltage of 15 kV. Kakanui hornblende (Harvard standard; USNM 143965) was the standard used during the analysis (five unknowns were analyzed between each standard analysis). The chemical composition for Kakanui hornblende along with the other standards used to calibrate for weight percent Al_2O_3 , FeO, K_2O , Na_2O , SiO_2 , CaO, MgO, MnO, and TiO_2 are listed in appendix B. Analyses were conducted as 5-point transects from rim to core to rim across single hornblende crystals to identify any heterogeneity in distribution of aluminum within the crystals. Five crystals were analyzed for each sample, however, only analyses from one crystal (5 data points) were used from Omar (appendix B; Omar-7a-e), as the other four crystals define compositions that are not typical hornblende due either to alteration, or accidental analysis on a phase other than hornblende.

Following electron microprobe analysis, weight percent data was converted into structural formulas by dividing the oxide values obtained for major elements by their atomic weight and then converting to a molar proportion. From the molar proportions, the oxygens are summed and divided by 23. This value is multiplied by the cations yielding the total aluminum per 23 oxygens, which is used in a calibrated barometry equation for estimating the pressure of emplacement. Errors at 1σ represent quadratic summation of microprobe and calibration uncertainties.

U/Pb Geochronology

Geochronology using the U/Pb isotopic system is probably the most accurate method of dating for rocks older than a few tens of millions of years (Moser and Scott, 2000; Ludwig, 1998). This is in part due to the availability of three isotopic ratios for use in age calculations: $^{238}\text{U}/^{206}\text{Pb}$, $^{235}\text{U}/^{207}\text{Pb}$, and $^{207}\text{Pb}/^{206}\text{Pb}$. For an ideal analysis, where the sample is concordant and undisturbed (i.e. closed system), all three systems will yield ages that are equal within analytical error (Ludwig, 1998).

Zircons have been widely used as a U/Pb geochronometer. Cherniak and Watson (2000) found extremely slow diffusion rates for Pb, indicating that zircons will remain closed systems under most crustal conditions. From this data the closure temperature for zircons of standard analytical size ($\sim 100\text{ }\mu\text{m}$) are in excess of $900\text{ }^{\circ}\text{C}$, whereas a typical crystallization temperature for granitic magmas is lower at $\sim 750\text{ }^{\circ}\text{C}$. Thus, for granitic magmas such as those in this study, zircons are immediately closed to U and Pb diffusion upon crystallization and are interpreted to record timing of crystallization for plutons. The closure temperature for zircon in this study is thus taken as $750\text{ }^{\circ}\text{C}$.

Two methods for determining U/Pb zircon ages are ion microprobe analysis and what is referred to as 'conventional' U/Pb dating. Conventional U/Pb dating is done using a thermal ionization mass spectrometer along with isotope dilution to determine isotopic ratios. Results from this method tend to be very precise, however accuracy may be compromised due to the presence of multiple U/Pb systems within single zircon crystals such as older inherited cores with younger overgrowths (Fig. 5). Analysis on a high-resolution secondary ion mass spectrometer has proven to be a more accurate method in obtaining U/Pb zircon ages in such cases (Williams, 1992). Accuracy is gained using this method because areas only tens of microns in diameter may be analyzed, which allows for direct analysis of distinct age domains within individual zircon crystals. Using the ion microprobe, accuracy is increased, although analyses tend to be less precise than the conventional method as a result of the small amount of sample being analyzed. Thus, for zircons with complex internal U/Pb systematics, relatively imprecise ion microprobe analyses could be more useful than high precision conventional analyses (e.g. Williams, 1992). The ion microprobe method was chosen for the U/Pb analyses conducted in this research.

Zircons were analyzed at the National Ion Probe facility at UCLA using a CAMECA ims 1270 high resolution, high sensitivity ion microprobe. The zircon standard used for these analyses was AS-3 which yields a conventional U/Pb age of 1099.1 ± 0.5 Ma (Paces and Miller, 1993). Twenty-six analyses of AS-3 gave a Pb-U calibration with slope = 0.34 ± 0.07 (1σ), y-intercept = 7.66 ± 0.49 (1σ), and an MSWD of 12.58. Because the samples in this study are Mesozoic in age, the data are presented using Tera-Wasserburg concordia U/Pb diagrams where the X-axis is $^{238}\text{U}/^{206}\text{Pb}$ and the

Figure 5. Example of inherited core with multiple U/Pb systems within a single zircon crystal. A. Cathodoluminescence image of zircon crystal from granodiorite prior to ion microprobe analysis. The crystal shows the presence of a distinct core within zoned overgrowths. B. Post-analysis SEM image of the same crystal. Analyses show an inherited core, yielding an age 50 Ma older than the rims.

Y-axis is $^{207}\text{Pb}/^{206}\text{Pb}$, allowing uncorrected $^{206}\text{Pb}/^{238}\text{U}$ points to define a linear array representing a mixing line between common Pb (y-axis) and age (x-axis) (Tera and Wasserburg, 1972). Tera-Wasserburg concordia diagrams have less correlated errors in the X- and Y-axis values making relative scatter of data points more evident (Ludwig, 2001). Also, for Mesozoic and Cenozoic samples, discordance is difficult to detect on conventional concordia plots due to the large uncertainties of $^{235}\text{U}/^{207}\text{Pb}$ ages and the relative linearity of concordia for young samples (few 100 Ma's). Linear regressions were done based on the MSWD criterion of Wendt and Carl (1991), where exclusion of analyses (inherited cores) was based on failure to obtain a statistically valid regression. The U/Pb zircon ages presented in this paper are uncorrected for common Pb and quoted at 1σ errors with decay constant errors included. Analytical data are presented in Appendix C.

$^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology

$^{40}\text{Ar}/^{39}\text{Ar}$ dating was developed as a variation of the K/Ar method, which is based on the decay of ^{40}K to ^{40}Ar ($t_{1/2} = 1250$ Ma), after it was found that during irradiation in a nuclear reactor, neutron interactions with ^{39}K produced ^{39}Ar (Merrihue, 1965; Merrihue and Turner, 1966). Through calibration of this conversion rate, both parent and daughter can be measured at the same time yielding more accurate and precise ages. Since this discovery, the $^{40}\text{Ar}/^{39}\text{Ar}$ method has become a widely applied technique for solving geologic problems (McDougall and Harrison, 1999).

There are numerous advantages in using the $^{40}\text{Ar}/^{39}\text{Ar}$ method over the K/Ar method. Among these is the ability to measure parent and daughter ratios accurately,

precisely, and simultaneously using a mass spectrometer. This is in contrast with K/Ar dating where these element abundances are measured on separate splits of the sample using different analytical techniques (McDougall and Harrison, 1999). $^{40}\text{Ar}/^{39}\text{Ar}$ dating thus allows for a smaller amount of sample for analysis. Another advantage is the incremental measurement of Ar released from the sample. Step heating yields several (usually 10 to 15) analyses for each sample, which allows for determining chemical information, argon distribution within the sample, and testing of the assumptions involved in K/Ar dating (McDougall and Harrison, 1999).

Principal assumptions applied to the K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods include (1) the decay rate for ^{40}K is known accurately and precisely and is independent of temperature, pressure, and composition; (2) the isotopic composition of K ($^{40}\text{K}/\text{K}$) is constant in nature, since it is never measured directly; (3) the ^{40}Ar measured in the sample has been generated only by in situ ^{40}K decay since the time of crystallization; or (4) corrections for any nonradiogenic ^{40}Ar initially present in a sample can be made; and (5) the sample must have been a closed system with no loss or gain of K or radiogenic Ar (McDougall and Harrison, 1999). These assumptions may be tested and (for some) assessed more readily by the $^{40}\text{Ar}/^{39}\text{Ar}$ method than the K/Ar method, thus providing the basis for determining the reliability and meaning of measured ages (McDougall and Harrison, 1999).

The closure temperature for argon in hornblende is $500 \pm 50^\circ\text{C}$ (McDougall and Harrison, 1999; Harrison, 1981). K-feldspar age spectra were modeled by the multi-diffusion domain model technique (when possible) (Lovera et al., 1989) to record a continuous cooling history from ~ 350 to $\sim 150^\circ\text{C}$ (Lovera et al., 1991; Lovera, 1992).

Closure temperatures for any K-feldspar sample unsuitable for multidiffusion domain modeling were calculated using equations from Dodson (1973), and following Harrison and McDougall (1982).

Analyses were done at the Nevada Isotope Geochronology Laboratory at the University of Nevada, Las Vegas using a MAP 215-50 mass spectrometer. The atmospheric $^{40}\text{Ar}/^{36}\text{Ar}$ ratio and corresponding mass discrimination (4 AMU) factors are measured weekly and are recorded in data tables for individual samples (Appendix D). Samples were irradiated for 7 hours in the Oregon State University Radiation Center TRIGA type reactor. Analyses on K-glass and CaF_2 fragments were used to determine correction factors for interfering neutron reactions on K and Ca. $(^{40}\text{Ar}/^{39}\text{Ar})_{\text{K}}$ values were 0.0132 ± 0.012 . Correction factors for Ca were $(^{36}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 2.77 \times 10^{-4} (\pm 2.28\%)$ and $(^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 7.44 \times 10^{-4} (\pm 0.37\%)$. J-factors (assigned 0.5% errors) were calculated using single crystal laser fusion of 3 to 5 Fish Canyon Tuff sanidines from each level of neutron flux throughout the irradiation package. Sample ages were calculated using an age of 27.9 Ma (Steven et al., 1967; Cebula et al., 1986) for the Fish Canyon Tuff sanidine. Plateaus are defined as three or more consecutive steps totaling at least 50% of the ^{39}Ar released with ages that overlap at 2σ analytical errors (excluding J error). Isochrons are defined by greater than three consecutive steps corresponding to at least 50% of the ^{39}Ar released, and follow the MSWD criterion of Wendt and Carl (1991).

K-feldspar Modeling

Heating schedules of 49 to 50 steps were used for step heating of K-feldspars. This allows for determination of argon diffusion parameters (frequency factor and activation energy) intrinsic to each sample (Lovera et al., 1989; Lovera et al., 1991).

Arrhenius plots of these data show a linear array for the low temperature steps of the heating schedule followed by a departure from linearity, which can be explained by multiple diffusion domain sizes within the sample (Lovera et al., 1989; Richter et al., 1991). The linear portion of the plots is produced by the smaller diffusion domain sizes, which are outgassed at low temperatures (Lovera et al., 1989). Multiple diffusion domain theory assumes that argon loss follows an Arrhenius Law, that the ^{39}Ar loss measured during step heating is by the same mechanism responsible for diffusive loss in nature, and implies that all domains have the same frequency factor (D_0 , which is expressed as a combined parameter with the diffusion domain size, D_0/r^2) and activation energy (E) (Lovera et al., 1989; Lovera, 1992; Lovera et al., 1993). Experiments performed by Lovera et al. (1993) have supported the assumption of the same activation energy in multiple domains and Lovera et al. (2002) and Richter et al., (1991) showed that samples with highly correlated age and diffusion properties exhibit laboratory argon release that replicates natural diffusion mechanisms.

Computer programs were used to model Arrhenius data, $\log t/r_0$, age spectra, thermal histories, and correlations between the laboratory results and modeled results (Lovera et al., 1989; Lovera et al., 2002). Acceptability of models was based on statistical criteria defined within the programs: only statistically valid models were returned and used.

Arrhenius data are modeled by applying the laboratory step-heating schedule (excluding steps above 1100 °C where K-feldspar melts and ceases to follow Arrhenius Law diffusive loss) to model domain distributions with the purpose of creating a domain distribution that will reproduce the Arrhenius data generated in the laboratory. Domain

distributions, expressed as $\log r/r_0$ vs. $\%^{39}\text{Ar}$ released plots, are also produced during this modeling. A correlation between the $\log r/r_0$ plots and age spectra is then determined to quantify the applicability of laboratory diffusion parameters to those in nature, with acceptable correlations of $C_{fg} > 0.8$ (Lovera et al., 2002). Since the age spectrum is a function of natural diffusion during geologic cooling, and the $\log r/r_0$ plot is generated in the laboratory (during a much shorter time scale) during heating, a high correlation indicates that laboratory diffusion is via the same mechanism as that in nature. When the lab and model distributions are in good agreement, cooling histories may be modeled to find those that produce an internal argon distribution that would reproduce the laboratory age spectra when modeled. A minimum of 20 cooling histories was used to define an acceptable cooling curve for a sample.

U-Th/He Geochronology

One of the first systems used by geochronologists to determine the ages of rocks was the production of ^4He from the decay of ^{238}U , ^{235}U , and ^{232}Th isotopes (^4He is also produced by decay of ^{147}Sm to ^{143}Nd , but this in insignificant amounts) (Rutherford, 1905; Strutt, 1905; Reiners, 2002). However, early studies yielded ages that were unexpectedly young (Hurley, 1954), leading to limited application and near abandonment of the U-Th/He method of dating. Renewed interest in the technique was inspired after Durango fluorapatite (Zeitler et al., 1987) and apatites from multiple geochemical environments (Lippolt et al., 1994) showed evidence suggesting ^4He ages may record cooling through a lower closure temperature ($\sim 100^\circ\text{C}$) rather than crystallization ages. Further investigation by Wolf et al. (1996) found that He diffusion in apatite followed a

linear Arrhenius relationship below 290 °C with an activation energy of ~150 kJ/mol, indicating a closure temperature of ~75 °C. This temperature was thought to be independent of chemical composition and grain size suggesting possible application of a single closure temperature to a broad range of samples. Applicability of the U-Th/He system to low temperature thermochronology (~70 to 200 °C) has presently been demonstrated using several mineral phases including apatite, zircon, and titanite (House et al., 1998; Reiners and Farley, 1999; Farley, 2000; Reiners et al., 2002).

Apatite U-Th/He analyses were done at the California Institute of Technology. The ^4He is extracted by degassing crystals encased in a small foil packet with a CO_2 or Nd-YAG laser. Measurements are made using a quadrupole mass spectrometer (to ~1% precision) following ^3He isotope dilution and cryogenic purification (Reiners, 2002). Following degassing, crystals are retrieved, dissolved, and analyzed by isotope dilution for U and Th using an ICP-MS with similar uncertainties. An additional step involved in calculating He ages is determining the α -ejection correction (Farley et al., 1996). Radiogenic ^4He is separated from parent U, Th, and decay chain isotopes with high kinetic energies (~4-5 MeV), resulting in long stopping distances (~10 to ~30 μm depending on density/ composition of stopping medium) (Farley et al., 1996; Reiners, 2002). The importance of α -stopping distances for He dating is the potential ejection of a significant portion of the total ^4He produced from the crystal leading to underestimated ages. The correction for α -ejection (known as F_t correction) is based on the surface to volume ratio of the crystal and the α -stopping distance where crystals with larger surface to volume ratios require larger corrections (Farley et al., 1996).

CHAPTER 5

GEOBAROMETRY RESULTS

Pressures were estimated using calibrations of Hollister et al. (1987) and Schmidt (1992). The Hollister et al. (1987) calibration ($P (\pm 1 \text{ kbar}) = -4.76 + 5.64Al_T$) was used for direct comparison with previous studies (Young and Wooden, 1988; Foster et al., 1989) where their equation was demonstrated to be applicable. The Schmidt (1992) calibration ($P (\pm 0.6 \text{ kbar}) = -3.01 + 4.76Al_T$) represents an improvement to the Hollister et al. (1987) calibration and was used to demonstrate any significant difference in pressure estimates between the two. Although more recent calibrations have been published, (Chapter 4), Schmidt (1992) was selected because other recent calibrations (Anderson and Smith, 1995; and Ague, 1997) require plagioclase analyses, which were not obtained in this study and the experimental calibration of Schmidt (1992) is consistent with earlier empirical and experimental calibrations of the barometer. The Johnson and Rutherford (1989) calibration focused on volcanic rocks (this study focuses on plutonic rocks), whereas Rutter et al. (1989) applied barometry to igneous rocks at pressures greater than 10 kbar, significantly deeper than the mid-crustal rocks exposed in the Mojave Desert region (Young and Wooden, 1988).

All crystal rims represent conditions at the final stage of crystallization when all required phases (plagioclase + K-feldspar + quartz + hornblende + biotite + sphene + magnetite) are most likely present, and are therefore most ideal for estimating pressures

at emplacement. For plutons in the Granite Mountains, the mean Al_T values from all analyses and those found using only rim analyses are indistinguishable demonstrating that rim Al_T values are representative. Mean rim Al_T values (1σ errors) are 1.63 ± 0.04 for the SW monzogranite sample, 1.62 ± 0.08 for the central granodiorite sample, and 1.56 ± 0.09 for NE quartz monzonite sample (Table 1). Of 10 rim analyses, 9 were used in calculating the mean value for the monzogranite. One analysis ($Al_T = 1.12$) was excluded because it is more than 2σ lower than the mean. Hornblende from the syenogranite in the southern Providence Mountains yielded Al_T values ranging from 1.07 to 1.29 based on five analyses across one hornblende from rim to rim. These data yield a mean Al_T of 1.14 ± 0.09 (1σ) (Table 1).

Using the Hollister et al. (1987) and Schmidt (1992) equations, these Al_T values yield pressures of ~4.0 to 4.8 kbar for the Granite Mountains samples and ~1.7 to 2.4 kbar for the southern Providence Mountains sample (Table 1). Pressures for the Granite Mountains samples all overlap at 1σ error, corresponding to mid-crustal depths of emplacement (14.5 to 17.1 km) assuming a 3.6 km/kbar lithostatic gradient (Table 1). Of these three samples, the northeastern quartz monzonite sample yields a slightly lower mean Al_T value. Although pressure/depth estimates overlap for all Granite Mountains samples, the lower Al_T value may be indicative of a slightly shallower emplacement depth than the central granodiorite and SW monzogranite, which appear to have been emplaced at equal depths (Table 1). The implications of these data are discussed in Chapter 8. Mid-crustal emplacement depths are consistent with estimates for Cretaceous plutons in this region based on previous studies (Foster et al., 1989; Young and Wooden, 1988).

Table 1. Mean Al_T values from rim analyses for Granite and Providence Mountains samples, mean pressures with 1σ total uncertainties (quadratic summation of analytical and calibration errors), and depth ranges using calibrations by Hollister et al. (1987) and Schmidt (1992). Depths were calculated using a 3.6 km/kbar lithostatic gradient. Both calibrations indicate mid-crustal emplacement for Granite Mountains plutons and shallow crustal levels for the southern Providence Mountains pluton

Sample	Mean Al_T	Mean Pressure (kbar)		Depth (3.6km/kbar)	
		Hollister et al. (1989)	Schmidt (1992)	Hollister et al. (1989)	Schmidt (1992)
SW monzogranite	1.63 ± 0.04	4.43 ± 1.02	4.75 ± 0.63	15.95 ± 3.67	17.10 ± 2.27
central granodiorite	1.62 ± 0.08	4.40 ± 1.04	4.72 ± 0.66	15.84 ± 3.74	16.99 ± 2.38
NE quartz monzonite	1.56 ± 0.09	4.03 ± 1.03	4.41 ± 0.67	14.51 ± 3.71	15.88 ± 2.41
Providence syenogranite	1.14 ± 0.09	1.68 ± 1.02	2.42 ± 0.64	6.05 ± 3.67	8.71 ± 2.30

Shallow crustal emplacement depths have been determined for Jurassic plutons in the southern Providence Mountains by Young and Wooden (1988) and Fox and Miller (1990). Five analyses from the syenogranite sample yield pressures of 1.68 ± 1.02 kbar (Hollister et al., 1987) and 2.42 ± 0.64 kbar (Schmidt, 1989) (Table 1). These data correspond to emplacement depths ranging from 6.05 to 8.71 km, which is consistent with the previous studies.

CHAPTER 6

GEOCHRONOLOGY RESULTS

U/Pb Zircon

The following sections refer to data tables in Appendix C for ion microprobe U/Pb analyses on zircons from the southwest monzogranite (Calvin), central granodiorite (Floyd), northeast quartz monzonite (Yoshi), and southern Providence syenogranite (Omar). All ages are uncorrected and errors are quoted at $\pm 1\sigma$.

Southwest monzogranite

Ten analyses were made from the SW monzogranite sample (Calvin). Two zircons with inherited cores yielding $^{238}\text{U}/^{206}\text{Pb}$ ages of 93.4 and 134.8 Ma (appendix C) were discovered. These two analyses were excluded after statistically invalid linear regressions were obtained. The remaining eight analyses ranging from 75 to 87 Ma define a concordia intercept age of 71.6 ± 2.7 Ma (1σ , MSWD = 1.30) (Fig. 6). Based on these data the age of intrusion and crystallization for the monzogranite pluton is 71.6 ± 2.7 Ma.

Central granodiorite

Nine zircon spots were analyzed from the granodiorite sample (Floyd). An inherited core with a $^{238}\text{U}/^{206}\text{Pb}$ age of 119.6 Ma (appendix C) was excluded after linear regression of all 9 analyses resulted in a high MSWD of 5.6. The remaining 8 analyses

Figure 6. Tera-Wasserburg U/Pb diagram for monzogranite zircons. Eight analyses yield a concordia intercept age of 71.6 ± 2.7 Ma. All errors reported are at 1σ .

Figure 7. Tera-Wasserburg U/Pb diagram for granodiorite zircons. Four analyses yields a concordia intercept age of 73.0 ± 5.5 Ma. All errors reported at 1σ .

ranging from ~73 to ~93 Ma, define a statistically valid intercept age of 67.5 ± 2.4 Ma (1σ) with an MSWD of 0.46. However, based on a $^{40}\text{Ar}/^{39}\text{Ar}$ age of 74.8 ± 0.4 Ma for hornblende from this sample (discussed in the next section) a crystallization age of 68 Ma is unlikely. Within this eight-point data set are two subsets (4 analyses in each) with age ranges of 73 to 76 Ma and 80 to 93 Ma. The younger subset consists of analyses with higher and very similar radiogenic yields. The older set defines a wider range of radiogenic yields and thus a better constrained line fit. The four younger analyses yield a concordia intercept age of 71.2 ± 4.5 Ma (1σ) with an MSWD of 0.24, which is concordant with the $^{40}\text{Ar}/^{39}\text{Ar}$ data. A linear regression using the older data points yields an indistinguishable intercept age of 73.0 ± 5.5 Ma (1σ) with an MSWD of 0.08 (Fig. 7). As this latter age is defined by a better-constrained linear regression because of the larger spread of the data points, it is therefore interpreted as the age of crystallization for the granodiorite.

Northeast quartz monzonite

Twelve spots were analyzed on zircons from the NE quartz monzonite sample (Yoshi). Four inherited Jurassic cores were found (157, 164, and 179 Ma) along with a young outlier yielding an age of ~61 Ma (appendix C). This anomalously young age is most likely a result of Pb loss. The remaining eight analyses ranging from 76 to 93 Ma yield a concordia intercept age of 76.0 ± 3.3 Ma (1σ) with an MSWD of 1.80 (Fig. 8). This sample was collected from a pluton mapped as Jurassic spotted quartz monzonite (Jsq) by Miller et al. (1985), however, these data indicate the pluton is Cretaceous. The age of crystallization for this pluton is interpreted as 76.0 ± 3.3 Ma.

Figure 8. Tera-Wasserburg U/Pb diagram for quartz monzonite zircons. Eight zircon analyses yield a concordia intercept age of 76.0 ± 3.3 Ma. All errors reported at 1σ .

Figure 9. Tera-Wasserburg U/Pb diagram for quartz monzonite in the southern Providence Mountains. Seven zircon analyses give a linear regression with a concordia intercept age of 151 ± 7.5 Ma. All errors reported at 1σ .

Syenogranite

Seven analyses from the syenogranite sample (Omar) from the Providence Mountains yield ages ranging from 163 to 212 Ma. These data define a concordia intercept age of 151 ± 7.5 Ma (1σ) with an MSWD of 0.64 (Fig. 9). This age is consistent within errors of U/Pb zircon and K/Ar biotite ages (162 to 164 Ma and 157 ± 4 respectively) reported by Miller et al. (1985) and is considered as the crystallization age for this pluton.

The zircon ages presented for the Granite Mountains plutons are all concordant with their $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende ages, which are reported in the following section. The zircon age determined for the syenogranite in the southern Providence Mountains is consistent with ages determined in previous studies of other Jurassic plutons in the region.

$^{40}\text{Ar}/^{39}\text{Ar}$ Results

Hornblende

The following sections refer to data tables in Appendix D for $^{40}\text{Ar}/^{39}\text{Ar}$ analyses on hornblende and K-feldspar from the SW monzogranite (Calvin), granodiorite (Floyd), NE quartz monzonite (Yoshi), and syenogranite of Quail Spring (Omar). All errors are quoted at $\pm 1\sigma$.

Southwest monzogranite

Hornblende from the SW monzogranite sample gave an ideal flat age spectrum after four slightly younger initial steps (Fig. 10). Steps 7 through 16 define a plateau age of 74.80 ± 0.42 Ma, accounting for 88.8% of ^{39}Ar released. This is indistinguishable

Figure 10. $^{40}\text{Ar}/^{39}\text{Ar}$ age spectrum and isochron for hornblende from monzogranite. Errors are quoted at 1σ .

Figure 11. $^{40}\text{Ar}/^{39}\text{Ar}$ age spectrum and isochron for hornblende from granodiorite. Errors are quoted at 1σ .

from the total gas age of 74.65 ± 0.42 Ma (appendix D). A valid isochron using steps 6 through 16 (92.3% of ^{39}Ar released) gave an age of 75.35 ± 0.40 Ma with an MSWD of 1.3. Due to the high radiogenic yields for these steps, the initial $^{40}\text{Ar}/^{36}\text{Ar}$ of 189 ± 21.5 is poorly constrained and significantly below the atmospheric ratio of 295.5, indicating it is clearly spurious. Because of the questionable $^{40}\text{Ar}/^{36}\text{Ar}$ intercept of the isochron and the high radiogenic yields indicating insensitivity to excess argon, the plateau age of 74.80 ± 0.42 Ma is interpreted as the timing of cooling through ~ 500 °C for the pluton. This age is nearly indistinguishable within 1σ errors from the U/Pb crystallization age of 71.6 ± 2.7 Ma which suggests intrusion and very rapid cooling through 500 °C.

Central granodiorite

After high initial ages of ~ 135 Ma and ~ 80 Ma, hornblende from the granodiorite sample gave a concordant flat age spectrum (Fig. 11). A plateau using 92.8% of the ^{39}Ar released during steps 6 through 13 gave an age of 76.46 ± 0.53 Ma, indistinguishable at 1σ errors from the 77.35 ± 0.53 Ma total gas age (appendix D). An isochron using the same steps as the plateau, gave an age of 76.54 ± 0.50 Ma with an MSWD of 1.14. Similar to hornblende from the southwest monzogranite pluton, the high radiogenic yields result in a poorly constrained initial $^{40}\text{Ar}/^{36}\text{Ar}$ of 287 ± 38 , but indicate no excess argon is present. Although the plateau and isochron ages are identical, the plateau age of 76.46 ± 0.53 Ma is taken as the best age for the pluton cooling through ~ 500 °C, because of the high radiogenic yields. The hornblende plateau age and the U/Pb zircon age of 73.0 ± 5.5 Ma are indistinguishable within 1σ uncertainty suggesting cooling through 500 °C upon intrusion.

Northeast quartz monzonite

A flat concordant age spectrum was obtained for hornblende from the quartz monzonite sample after a high initial age of ~104 Ma (Fig. 12). Steps 7 through 14, representing 77% of the ^{39}Ar released, yield a plateau age of 77.38 ± 0.11 Ma, which is slightly younger than the total gas age of 78.65 ± 0.43 Ma (appendix D). An isochron was obtained using steps 6 through 9, accounting for 39.5% of the ^{39}Ar released, giving an age of 76.57 ± 0.90 Ma. The isochron $^{40}\text{Ar}/^{36}\text{Ar}$ intercept of 388 ± 40 indicates the presence of excess argon in this sample. The isochron for the sample is considered the best estimate of the age because of the presence of excess argon. Within 1σ errors the isochron age and the U/Pb zircon age of 76.0 ± 3.3 Ma are concordant. These ages suggest that the quartz monzonite pluton intruded, crystallized, and rapidly cooled through ~500 °C.

Southern Providence syenogranite

Hornblende from a syenogranite sample from the southern Providence Mountains yielded a very discordant age spectrum with ages ranging from ~755 Ma to ~168 Ma (Fig. 13). The total gas age for the sample is 286.23 ± 1.42 Ma and there is no plateau (appendix D). The “saddle-shape” of the age spectrum may indicate the presence of excess argon in the sample, however no valid isochron was obtained to verify this. For samples such as this, the minimum age on the spectrum (168.3 ± 1.5 Ma) is interpreted as a maximum age for the sample. This interpretation is consistent with the younger U/Pb zircon age of 151 ± 7.5 Ma. Since zircon has a higher closure temperature for Pb (>900 °C) than hornblende does for Ar (500 °C), the older ages recorded in the $^{40}\text{Ar}/^{39}\text{Ar}$ age spectra are likely to be artifacts due to excess argon.

K-feldspar

Southwest monzogranite

K-feldspar from the SW monzogranite sample gave a relatively flat age spectrum (Fig. 14). The first 0.5% of the ^{39}Ar released showed an age variation from ~106 Ma to ~64 Ma (appendix D), which is probably a result of low temperature release of a very small amount of fluid inclusion hosted excess argon. The second of the isothermal duplicates (555 – 720 °C) gave lower ages (~1-2 Ma) than the first step ages (appendix D). Apparent ages from the 761 °C step through melting and fusion (> 1100 °C) gave a subtly increasing ages from ~70 to ~72 Ma for the remaining 90% of the ^{39}Ar released. The resulting flat age spectrum gave a total gas age of 71.01 ± 0.35 Ma and is indicative of fast cooling, which is further discussed in chapter 7.

Central granodiorite

After an initial ~98 Ma step (0.2% of ^{39}Ar), the apparent age spectrum exhibits ages increasing in age from ~65 in low temperature steps to ~73 Ma in high temperature steps (Fig. 15). Isothermal duplicates showed very little variation in apparent ages indicating no excess argon (appendix D). The age spectrum yields a total gas age of 70.73 ± 0.35 Ma. Although this age spectrum is not as flat as the age spectrum for K-feldspar from the SW monzogranite, it also suggests relatively rapid cooling.

Northeast quartz monzonite

A gradually increasing age spectrum from ~67 to ~75 Ma resulted after a high initial step (~220 Ma) and minor variation in apparent ages during early isothermal duplicates (473-596 °C; appendix D) (Fig. 16). Apparent ages for this pluton are slightly older than those for the monzogranite and the granodiorite after step 25 (1002 °C)

resulting in a steeper age gradient in the spectrum and an older total gas age; 72.32 ± 0.36 Ma. The slope of the age spectrum suggests somewhat slower cooling than the other plutons.

Southern Providence syenogranite

K-feldspar from the syenogranite in the southern Providence Mountains shows ages ranging from 294 Ma to 75 Ma over the first 6% of ^{39}Ar released (appendix D; Fig. 17). The highest ages are during the first of the isothermal duplicates and represent a relatively large amount of excess argon being released from inclusions. After the varying initial isothermal steps, apparent ages increase from ~77 to ~127 Ma over the next 35.5% of ^{39}Ar released (appendix D). The total gas age for the sample is 119.9 ± 0.6 Ma. Overall this age spectrum is very discordant compared to the Granite Mountains samples. A weighted mean age of 86.49 ± 0.24 Ma corresponding to a closure temperature of 210 ± 40 °C was calculated using steps 2 through 5. This age is significantly older than those from Granite Mountains K-feldspar samples. The relatively low radiogenic yields obtained for steps 2 through 5 may indicate these ages are affected by excess Ar (appendix D) (Chapter 7) and is discussed further in chapter 7.

U-Th/He Apatite

The ages determined using two single crystal analyses for each sample are: 23.6 ± 0.8 Ma from the SW monzogranite pluton:, 40.2 ± 3.3 Ma from the central granodiorite pluton:, 21.2 ± 2.2 Ma from a NE quartz monzonite pluton:, and 35.1 ± 2.3 Ma from syenogranite in the southern Providence Mountains: (all errors at 1σ ; appendix E). These data exhibit a positive correlation between age and elevation (Fig. 18), which may

Figure 18. Plot showing correlation between U-Th/He ages and present elevation for samples from the Granite and southern Providence Mountains.

be explained by either very slow cooling following Late Cretaceous tectonics or a prolonged residence in the He partial retention zone.

CHAPTER 7

THERMAL HISTORIES

K-feldspar Multidomain Modeling

Southwest monzogranite

The initial low temperature linear array of the Arrhenius plot (steps 2 through 6) gave an activation energy (E) and D_0/r^2 of 168.6 kJ/mol and 755.4 s^{-1} , respectively (Fig. 19a). The model Arrhenius data, $\log r/r_0$ (domain distribution plot), and age spectra all show good agreement with the sample data (Fig 19 a-c). A high correlation coefficient of 0.87 between the $\log r/r_0$ plot and age spectrum indicates the relevance of the laboratory diffusion with that in nature (Lovera et al., 2002). The modeled age spectra (Fig. 19c) corresponding to the 20 cooling histories are shown in Fig. 19d. The upper and lower limits of model cooling curves are constrained by closure temperatures calculated for the estimated diffusion domains (Table 2). The model cooling histories are highly reproducible (Fig. 20a) and define a well-constrained cooling curve showing rapid cooling from 303 to 183 °C between 71.0 and 69.1 Ma (Fig. 19d & 20a). This corresponds to a cooling rate of 63.2 °C/Ma, and a denudation rate of 2.1 mm/yr (assuming a 30 °C/km geothermal gradient) between 71.0 and 69.1 Ma.

Figure 20. 90% confidence intervals for K-feldspar cooling curves for SW (A), central (B), and NE (C) plutons. Blue indicates 90% confidence that a modelled cooling curve will fall within the region. Yellow shows 90% confidence where the mean of a new series of models will fall.

Central granodiorite

An activation energy of 160.0 kJ/mol and D_0/r^2 of 820.2 s^{-1} was determined from steps 1 through 4 on the Arrhenius plot for K-feldspar from the central granodiorite (Fig. 21a). As with K-feldspar from the SW monzogranite pluton, modeled Arrhenius data, log r/r_0 plot, and age spectra for the granodiorite show very good agreement with sample data (Fig. 21a-c). Log r/r_0 and age spectra plots have a correlation coefficient of 0.93 supporting consistency between diffusion in the laboratory during step heating and diffusion in nature. Thirty-three modeled cooling histories were produced along with their corresponding age spectra (Fig. 21c,d). The cooling curves define a tightly constrained thermal history (Figs. 21d & 20b) indicating cooling from 293 to 157 °C between 71.6 and 67.3 Ma. This corresponds to a cooling rate of 31.6 °C/Ma or denudation rate of 1.1 mm/yr.

Northeast quartz monzonite

Steps 2 through 12 of the Arrhenius plot for K-feldspar from the quartz monzonite pluton yield an activation energy and D_0/r^2 values of 151.0 kJ/mol and 46.3 s^{-1} , respectively (Fig. 22a). Laboratory and modeled Arrhenius data, log r/r_0 plot, and age spectrum are in very good agreement (Fig. 22a-c). The log r/r_0 plot and age spectrum have a correlation coefficient of 0.98, supporting confidence in the models and the relevance of laboratory diffusion properties to nature. Along with their respective age spectra, twenty-eight modeled cooling histories were obtained, defining a well-constrained (Figs. 22d, 20c) thermal history from 251 to 145 °C between 72.9 and 66.2 Ma (Fig. 20d). A cooling rate of 15.8 °C/Ma and denudation rate of 0.5 mm/yr can be interpreted from these cooling curves.

Southern Providence syenogranite

K-feldspar from the syenogranite in the southern Providence Mountains was not suitable for multi-domain modeling. The $\log r/r_0$ and age spectra correlation was very poor at 0.19 indicating this sample does not conform to the assumptions of the multi-diffusion domain model (Fig. 23). However, the low temperature diffusion data do provide for an interpretation of this sample. An activation energy of 150.6 kJ/mol and D_0/r^2 of 42.3 s^{-1} was obtained from the steps 2 through 5 of the Arrhenius plot corresponding to the second of the isothermal duplicates from 473 to 596 °C (Fig. 23a). These diffusion parameters were used to calculate a closure temperature of $210 \pm 41 \text{ °C}$ (Dodson, 1973; Harrison and McDougall, 1982). These steps yield a weighted mean age of $86.5 \pm 0.2 \text{ Ma}$, which is associated with the calculated closure temperature. However, due to the relatively low radiogenic yields of these steps, it is possible that this age is affected by excess argon and thus, older than the actual age.

Construction of Thermal Histories

Isotopic ages combined with closure temperatures specific to the phases dated allow reconstruction of the thermal histories for these samples. When used together, the three isotopic systems; U/Pb, $^{40}\text{Ar}/^{39}\text{Ar}$, and U-Th/He, yield a cooling history from intrusion and crystallization at depth to cooling through 70 °C (near surface). Cooling rates from sections of the cooling curves can be used to identify periods of rapid tectonic denudation (rapid cooling) as well as slower regional erosional exhumation (slower cooling), estimate the rates at which these events occur, and the timing of transitions

Figure 23. Arrhenius plot (A) and domain size distribution diagram (B) for K-feldspar from syenogranite in the southern Providence Mountains. Poor agreement between model and sample is apparent. The correlation coefficient of 0.19 between the age and $\text{log } r/r_0$ spectra supports the inapplicability this K-feldspar for multi diffusion domain modeling.

between them. A description of the thermal histories obtained is presented here while implications for these histories will be discussed in chapter 8.

Southwest monzogranite

The reconstructed thermal history for the SW monzogranite sample is presented in Figure 24. Zircon and hornblende ages are indistinguishable, indicating intrusion and geologically instantaneous cooling from 750 to 500 °C. From ~75 to 71.0 Ma the pluton underwent rapid cooling at ~49 °C/Ma down through ~303 °C, where the K-feldspar began recording. This was followed by an interval of cooling at ~63 °C/Ma from 71.0 to 69.1 Ma as defined by the K-feldspar (Fig. 24). Slow cooling through ~70 °C at ~1.8 °C/Ma is indicated by the ~23.6 Ma U-Th/He apatite age. These data define a significant break in the cooling history at ~69 Ma from rapid cooling through K-feldspar closure to very slow cooling (1.8 °C/Ma) over the interval of ~69 to ~24 Ma.

Central granodiorite

Figure 25 shows the reconstructed thermal history for the granodiorite pluton. As for the southwest monzogranite pluton, emplacement, crystallization, and geologically instantaneous cooling through 500 °C upon intrusion is suggested by the indistinguishable zircon and hornblende ages. Cooling from 500 °C through 293 °C between ~75 and 71.6 Ma occurred at a rate of ~60 °C/Ma. K-feldspar models suggests a rate of cooling from 71.6 to 67.3 Ma at ~32 °C/Ma over a temperature interval of 293 to 157 °C. An apatite age of ~40.2 Ma indicates cooling through 70 °C occurred following a period of slow cooling (3.2 °C/Ma) from ~67 to ~40 Ma.

Figure 24. Thermal history for a sample from the southwest Granite Mountains. Error boxes for ages are 1σ . Dark gray region indicates the path of cooling through data points for the pluton. Dashed light gray region indicates most probable cooling path during emplacement. Initial rapid cooling was followed by final slow cooling episode.

Figure 25. Thermal history for a sample in the central Granite Mountains. Error boxes for ages are 1σ . Dashed light gray region indicates the most likely path of cooling for the pluton from intrusion through 500 °C. The rapid cooling recorded in the K-feldspar is followed by a break to slow cooling through 70 °C.

Northeast quartz monzonite

The thermal history for the NE quartz monzonite (Fig. 26) is similar to the other Granite Mountains plutons, suggesting emplacement and instantaneous cooling through 500 °C at ~75 Ma. Following this initial cooling continued rapid cooling occurred (>100 °C/Ma) through ~251 °C for this sample. K-feldspar modeling indicates cooling from ~251 to ~145 °C occurred at a somewhat lower rate of ~16 °C/Ma from 72.9 to 66.3 Ma. The ~21.2 Ma apatite age (indistinguishable from that of the SW monzogranite) indicates an interval (~66 to 21 Ma) of slow cooling (1.7 °C/Ma) prior to cooling through ~70 °C.

Southern Providence syenogranite

The thermal history for the syenogranite from the southern Providence Mountains is shown in figure 27. Intrusion occurred at 151 Ma as defined by the U/Pb zircon age. Figure 27 shows a dark and light gray path for cooling down to 210 °C (K-feldspar closure). The darker path is a simple connection of data points; the dashed light gray path is a more probable path. The K-feldspar closure temperature of 210 °C corresponds to 7 km depth (assuming 30 °C/ km geothermal gradient) and may define a lower boundary for depth of emplacement whereas the upper boundary is defined by geobarometry indicating intrusion at < 10 km (300 °C). Thus, a pluton intruded within this temperature range would undergo geologically instantaneous thermal equilibration with country rock, at ~300 to 210 °C (Chapter 8) and would remain isothermal or continue cooling at an extremely slow rate (dependent upon regional surface erosion rates). The syenogranite pluton underwent continued slow cooling at ~2.8 °C/Ma following K-feldspar closure from 86 to 35 Ma when the pluton cooled through U-Th/He apatite closure at ~70 °C.

Figure 26. Thermal history for a sample from the northeast Granite Mountains. Error boxes for ages are 1σ . Dark gray region shows cooling path. Dashed light gray area indicates the likely cooling path upon emplacement. Rapid initial cooling followed by slow cooling over ~40 Ma through 70 °C.

Figure 27. Thermal history for a sample from the southwest Providence Mountains. Dark gray region is inferred cooling history by simply connecting data points. Dashed light gray region is the more likely path, due to shallow crustal emplacement depths. Minimum age of ~74 Ma for K-feldspar likely indicates complete degassing of a domain due to reheating by Granite Mountains plutons. Error boxes for ages are 1σ .

As mentioned in chapter 6, the 86 Ma age for the K-feldspar may be an overestimate caused by excess argon. Another interpretation may be that the slope of the age spectrum is indicative of argon loss during a younger reheating event. The second of several isothermal duplicates yield Late Cretaceous ages with a minimum age of ~74 Ma, which may represent resetting of small domains during this event which at 74 Ma, corresponds with emplacement of Cretaceous plutons in the neighboring Granite Mountains. In this case, the thermal history for this sample would most likely exhibit slow cooling to ~200 °C until ~75 Ma where temperature would increase due to reheating (Fig. 27) before continuing to cool slowly through 70 °C.

Granite Mountains plutons

Common to all three Granite Mountains samples is intrusion at ~75 Ma with geologically instantaneous cooling through 500 °C, followed by continued rapid cooling through ~150 °C at ~66-69 Ma. Geologically instantaneous cooling through ~500 °C upon emplacement is expected for magma bodies intruded at mid-crustal levels (assuming a 30 °C/km geothermal gradient, e.g., 13 km = 390 °C), as indicated by geobarometry (Chapter 8). However, it should be noted that with a lower geothermal gradient of 25 °C/km, cooling would still be interpreted as conductive, but with a slightly higher geothermal gradient of 35 °C/km, cooling through hornblende closure may be interpreted as tectonic. The time interval between hornblende closure and initial K-feldspar closure for the three Granite Mountains samples supports a geothermal gradient >20 °C/Ma. Rapid cooling continues through ~150 °C following thermal equilibration at intrusion. This continuation of rapid cooling is indicative of continued denudation since the plutons continue to cool rapidly to well below mid-crustal temperatures.

Denudation is interpreted as tectonic as opposed to erosional because juxtaposition of different crustal levels (mid and shallow) is involved. This period of extremely fast cooling in the Late Cretaceous was followed by a distinct break to a very slow cooling interval lasting through the Oligocene. Slow cooling during the Tertiary is also seen in the thermal history for the syenogranite in the southern Providence Mountains (Fig. 27), suggesting regional slow cooling during tectonic quiescence.

CHAPTER 8

DISCUSSION

Emplacement depths for plutons

Geobarometry (Chapter 5) indicates mid-crustal emplacement depths for Late Cretaceous plutons of the Granite Mountains (~14 to 17 km) and shallow crustal depths for a Late Jurassic pluton from the southern Providence Mountains (~6 to 9 km). These estimates are similar to those of previous studies of Mesozoic plutons in the area (Young and Wooden, 1988; Fox and Miller, 1990).

Young and Wooden (1988) determined mid-to-deep crustal emplacement depths for both Jurassic and Cretaceous plutons in the Granite Mountains as well as Cretaceous plutons in the nearby Old Woman Mountains (Figs. 2, 3). These estimates were derived using the aluminum-in-hornblende geobarometer, phengite-muscovite, and plagioclase-garnet-muscovite-biotite equilibria barometers, which all yielded pressures of 5 to 7 kbar (19 to 25 km) for the Old Woman granodiorite (Young and Wooden, 1988). Jurassic and Cretaceous plutons in the Granite Mountains yield crystallization pressures of 6.0 to 7.5 kbar based on aluminum-in-hornblende barometry (Young and Wooden, 1988). In this study, analyses on hornblende from Late Cretaceous plutons in the Granite Mountains yielded Al_T values ranging from ~1.5 to ~1.6 (Table 1), which suggests slightly shallower depths of emplacement (14 to 17 km) compared to those determined by Young and

Wooden (1988) also using the aluminum-in-hornblende barometer. The Cretaceous pluton studied by Young and Wooden (1988) yielded a U/Pb age of 136 ± 6 Ma and may indicate the Jurassic plutons remained at or near their emplacement depth into at least the Early Cretaceous before regional contractional tectonics occurred placing these plutons at slightly shallower depths by the Late Cretaceous when the ~4.0 to 5.0 kbar plutons analyzed in this study intruded.

Young and Wooden (1988) reported emplacement pressures of ~3 kbar (10.8 km) for plutons in the southern Providence Mountains, whereas emplacement depths of less than 10 km were estimated by Fox and Miller (1990) using field relations and mineralogic data. Emplacement depths determined for the syenogranite pluton in this study (6 to 9 km) are consistent with these previous studies. The $^{40}\text{Ar}/^{39}\text{Ar}$ K-feldspar data for this pluton, which corresponds to a closure temperature of ~210 °C at 86.5 Ma (Fig. 27), may also provide constraints on emplacement depth. Although the 86.5 Ma age may be an artifact of excess Ar, the reconstructed thermal history (Fig. 27) suggests emplacement at temperatures > 210 °C because K-feldspar closure (~210 °C) didn't occur until ~65 Ma after emplacement at 151 Ma. Foster et al. (1992) suggest a minimum geothermal gradient of 25 °C/km in the nearby Old Woman and Piute Mountains area prior to extensive Late Cretaceous magmatism. Assuming a 30 °C/km geothermal gradient, this suggests emplacement depths greater than 7 km (210 °C). Therefore, the syenogranite pluton in the southern Providence Mountains was likely emplaced between 7 and 9 km depth.

For the Granite Mountains, the Hollister et al. (1987) and Schmidt (1992) results (Table 1) are indistinguishable within the resolution of their calibrations, and are

consistent with previous studies. However, the slightly lower Al_T value for the NE quartz monzonite may be indicative of shallower emplacement relative to plutons to the SW. Present elevations of samples argue against this, as the northeast sample was taken from the lowest elevation (1217 m) and the central granodiorite sample from the highest (1847 m). Without faulting between them or tilting of the entire section, sample elevations should reflect emplacement depth, however, the NE quartz monzonite is separated from the other plutons by a north-to-northwest-striking down-to-the-northeast normal fault (Fig. 2). Therefore, it is possible that the NE pluton was subsequently down dropped from a higher elevation to its present elevation following emplacement. The age-elevation correlation of the U-Th/He apatite ages indicates any displacement along this fault would have occurred before ~40 Ma. If the sample was emplaced shallower than samples to the southwest, >0.6 km of displacement on the fault is necessary. However, these small apparent differences in emplacement depths cannot be resolved with the geobarometry due to uncertainties of ± 1 kbar and ± 0.6 kbar in the Hollister et al. (1987) and Schmidt (1992) calibrations, respectively.

U/Pb zircon and $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende ages, along with geobarometry, may also have implications for emplacement depths. The geobarometry suggests emplacement of plutons at 14.5 to 17.1 km depth (Table 1) corresponding to country rock temperatures of 435 to 513 °C, assuming a 30 °C/km geothermal gradient. Emplacement at temperatures less than 500 °C could explain the indistinguishable zircon and hornblende ages as rapid cooling due to conductive heat loss. Conductive cooling models for magma bodies ~10 km in diameter with initial temperatures of 750 °C indicate crystallization and cooling through 500 °C after only several 100 ka when emplaced in ~450 °C country rock, which

is within the uncertainties of the zircon and hornblende ages. Due to the uncertainties associated with U/Pb and $^{40}\text{Ar}/^{39}\text{Ar}$ ages, such a rapid interval of cooling through 500 °C is not resolvable, and thus interpreted as geologically instantaneous. The barometry allows for the plutons to be emplaced at slightly greater than 500 °C (Table 1), in which case denudation would be necessary to explain the rapid cooling through 500 °C. However, the barometry generally suggests emplacement at ~500 °C or lower, thus conductive heat loss upon intrusion is likely the best explanation for the rapid cooling through hornblende closure (500 °C).

Intrusion and exhumation of the Granite Mountains plutons

The three Granite Mountains samples forming a transect from southwest to northeast across the range (Fig. 2) were emplaced at 72 to 76 Ma as indicated by U/Pb zircon ages. Geobarometry and conductive cooling models suggest the rate of cooling through 500 °C following emplacement was very rapid, which is consistent with the indistinguishable hornblende and zircon ages. As a result of the dating techniques, the $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende ages are significantly more precise than the U/Pb ion probe zircon ages. Thus, these ages suggest intrusion, crystallization, and initial cooling through 500 °C likely occurred at ~75 Ma (74 to 76 Ma) (Figs. 24-26).

Conductive cooling models indicate very rapid cooling to mid-crustal country rock temperatures where, in the absence of tectonic activity, the plutons would remain isothermal. If this occurred, the cooling history would follow an exponential curve with the cooling rate decreasing rapidly as thermal equilibration with country rock is approached (Fig. 28). The continued rapid cooling from 500 °C to initial K-feldspar

Figure 28. Comparison of reconstructed thermal histories with conductive cooling models. SW=southwest monzogranite, CG=central granodiorite, NE=northeast quartz monzonite. Red curves represent conductive cooling paths for plutons emplaced at ~75 Ma at 17 km (510 °C) and 14.5 km (435 °C) with a geothermal gradient of 30 °C/km and green curves represent conductive cooling paths for plutons emplaced at 14.5 km assuming 20 °C/km (300 °C) and 25 °C/km (363 °C) geothermal gradients. With a 30 °C/km gradient, continued rapid cooling following hornblende closure (500 °C) clearly indicates tectonic denudation . The time interval between hornblende closure and initial K-feldspar closure indicates the geothermal gradient was > 20 °C/km. Continued denudation is still evident with a geothermal gradient lower than 30 °C/km.

Figure 28.

closure and the cooling intervals (~300 to 150 °C) recorded by the K-feldspar models (63 to 16 °C/Ma) is therefore indicative of exhumation. Tectonic exhumation is favored over erosional exhumation due to the rapid cooling rates as well as the cooling rate gradient across the range. Cooling rates recorded in K-feldspar models do not exceed observed erosional rates. However, the significant change in cooling rate recorded in MDD models (which includes crossing over of cooling curves) across only ~10–15 km lateral distance, indicates that climatic changes resulting in evolving erosion rates are unlikely. It is therefore interpreted that the three Granite Mountains plutons were intruded syntectonically in the Late Cretaceous at ~75 Ma. Tectonic activity probably ceased around 66 Ma, at the time K-feldspars ceased recording (Fig. 24-26, 28). This interval of rapid cooling was followed by a break to slow cooling (<3.2 °C/Ma) indicating a period of tectonic quiescence through the late Eocene to the early Miocene, when plutons were within a few km's of the surface and beginning to cool through 70 °C (Figs. 24-26).

Rapid tectonic exhumation from ~75 to 66 Ma in the Granite Mountains correlates well in the east Mojave Desert region with timing of rapid exhumation for the Old Woman granodiorite due to movement on the Old Woman shear zone at 73 to 68 Ma (Foster et al., 1989; Foster et al., 1992), extension and unroofing along the Pinto Shear zone from 71 to 65 Ma (Beyene, 2000), movement on the East Providence fault zone at ~70 Ma (Miller et al., 1995), and unroofing in the Funeral Mountains of Death Valley from 72 to 70 Ma (Applegate et al., 1992).

Tectonic implications from K-feldspar multi-domain modeling

During extensional tectonism and normal faulting, footwall rocks are moved up relative to hanging wall rocks. Normal faulting thus places deeper-seated rocks (hotter) in the footwall against shallower rocks (cooler) in the hanging wall. This results in heating of the hanging wall and refrigeration of the footwall due to the temperature gradient between the juxtaposed rocks, a phenomenon that may explain the post-intrusional cooling from 500 °C to ~150 °C in the Granite Mountains. Several possible scenarios may explain the reconstructed thermal histories of the Granite Mountains plutons including exhumation by a single normal fault, tilting of a crustal section, and conjugate normal faulting.

Exhumation by a single normal fault

The extremely rapid K-feldspar cooling curve for the SW pluton suggests a single fault model to be a down-to-the-southwest normal fault with the Granite Mountains in the footwall. Exhumation by such a fault would require the NE quartz monzonite pluton to be emplaced at significantly shallower depths than the central and SW plutons to account for the rapid cooling through initial K-feldspar closure (251 °C at 72.9 Ma) while other samples were at >375 °C (Figs. 20, 24-26). However, the aluminum-in-hornblende geobarometry does not suggest any significant differences in emplacement depth. If the NE pluton was emplaced at 14.5 km (435 °C), which is the minimum depth based on geobarometry (Table 1), with other plutons at deeper levels, proximity to a fault would be necessary to explain the rapid cooling below 300 °C that was not recorded in the central and southwest samples until ~ 2 Ma later (Fig. 24-26). A detachment fault exhibiting flexural rotation of the footwall may accommodate earlier cooling of the NE if the

samples were emplaced at progressively greater depths from NE to SW (Buck, 1988). Upon rotation of the footwall, motion will cease along the low angle portion of the fault accounting for the slow cooling in the NE (Buck, 1988). Isostatic rebound of the footwall due to removal of the upper plate could provide a significant upward motion that may account for the rapid cooling in the SW and also explain the present day sample elevations. However, a single fault model does not seem to account for the juxtaposition of the mid-crustal Granite Mountains and the shallow-crustal southern Providence Mountains. Therefore, a second fault dipping northeast with the Granite Mountains in the footwall appears to be necessary.

A tilted crustal section

Lateral exposure of mid-crustal and shallow-crustal rocks at the surface may be indicative of a tilted crustal section. The four samples used in this study are all located laterally > 4.5 km from each other. Restoration of tilting would result in progressively shallower crustal levels (lateral distances reflected as differences in depth) with the southwest monzogranite sample deepest, and the southern Providence syenogranite shallowest (Fig. 29). A problem with this model is that differences in emplacement depths greater than 4.5 km should be resolvable by the geobarometry, however there is no evidence for significant differences in emplacement depth from the data (Table 1). Significant differences in emplacement depth may be inferred when using upper and lower limits of the uncertainties, however this approach seems to demonstrate poor confidence in the technique.

Alternatively, the plutons of the Granite Mountains could be emplaced next to and progressively (but not significantly) deeper than those in the southern Providence

Figure 29. Schematic representing a tilted crustal section with model cooling rates shown. Red squares represent present elevation and map distance between samples from SW to NE. Blue squares represent paleodepth/temperature determined by geobarometry. Linear regression through blue squares represents sample positions before tilting assuming a linear depth profile between samples based on apparent linear relationship between present sample elevations/locations. Cooling rates for each sample are based on interval from 75 to 68 Ma, when the southwest monzogranite would have cooled through ~ 150 °C. Model cooling rates for the central and northeast Granite Mountains samples are significantly higher than those determined by K-feldspar modeling (Figs. 21, 29, 30). K-feldspar models also suggest earlier cooling through 150 °C for the southwest Granite Mountains, which is not apparent in the tilted section model.

Mountains (Fig. 29). The present day sample locations/elevations allow for the assumption of a linear spatial relationship relative to depth between the samples at the time of emplacement (Fig. 29). Since only hydrothermal alteration has been described in the Providence Mountains, an assumption is made for this model that the plutons are slightly shallower than their original emplacement depth by Late Cretaceous time and have not been significantly buried following intrusion. The U-Th/He ages also provide a lower limit to the depth of the plutons at this time. Tilting, and thus exhumation, of the samples up to ~5 km depth (end of K-feldspar models) over the interval 75 to 68 Ma (timing of southwest sample to cool through 150 °C) suggests cooling rates significantly higher than those indicated by the reconstructed thermal histories for the central and northeast samples (Figs. 29, 30). Also, the southwest sample would be expected to cool through lower temperatures later than samples to the northeast, however K-feldspar models indicate the southwest sample cooled through ~180 °C while other samples were at 200 °C or greater (Fig. 30). Overtilting followed by backtilting would be necessary to accommodate this more rapid cooling through low temperatures in the SW and present day sample elevations. The inconsistency of the reconstructed thermal histories with those expected from the tilted section model suggests lateral juxtaposition of the deeper-seated Granite Mountains with the shallow crustal southern Providence Mountains is most likely a result of faulting between them, and not tilting of a crustal section.

Exhumation by conjugate faulting model

K-feldspar thermal models indicate a distinct cooling rate gradient across the Granite Mountains. From southwest to northeast, samples record cooling rates of 63, 32 and 16 °C/Ma between ~300 and 150 °C (Figs. 2, 20, & 30). These correspond to

Figure 30. Cooling curves from K-feldspar multidomain modeling for three Granite Mountains plutons. Plot shows the changes in cooling rates across the Granite Mountains from the southwest to the northeast. The northeast began to cool through lower temperatures earlier than the others, whereas samples to the southwest cooled later and faster.

denudation rates of 2.1, 1.1, and 0.5 mm/yr assuming a 30 °C/km geothermal gradient. Advection of geotherms is expected when denudation rates exceed ~1 mm/yr (Stuwe et al., 1994). The implications of advection are that the cooling rates determined from thermochronology may not reflect motion of the plutons to the surface, but rather cooling during relaxation of compressed geotherms after rapid tectonic emplacement in the shallow crust. However, a significant tectonic event is necessary to explain the rapid cooling rates, regardless of which case they represent.

K-feldspar models show that cooling was fastest to the southwest (63 °C/Ma), where K-feldspar recording began later (71.0) and ended earlier (69.1 Ma) than in the northeast. The NE K-feldspar sample indicates the NE Granite Mountains began to cool earlier than the southwest, more slowly, and over a longer period of time (72.9 to 66.2 Ma; 16 °C/Ma) (Figs. 20 & 30). A model in which two faulting events occurred may explain this cooling pattern. It should be noted however, that the structures proposed below that may have existed have since been removed by erosion, although a breccia zone in Granite Pass may be a remnant of one of the proposed faults.

The northeast Granite Mountains cooled through ~250 °C while other samples to the SW were still at >375 °C (Fig. 28). Proximity to a normal fault may explain this earlier stage of cooling, as geobarometry indicates no significant difference in emplacement depth for the three samples. This normal fault would most likely be north to northwest striking with the Granite Mountains in the footwall and the Providence Mountains in the hanging wall. The fault in Granite Pass (Fig. 2) (Howard and Miller, 1992) may represent this structure. Two-dimensional thermal modeling indicates a normal fault dipping ~65 ° NE with a slip rate of 3.5 mm/yr from 76 to 74 Ma will

accommodate juxtaposition of the Granite Mountains with the southern Providence Mountains and reproduce the higher temperature segments (~500 to 350 °C) of the reconstructed thermal histories (Figs. 31 and 32). The interval 76 to 74 Ma represents cooling through 500 °C and initial K-feldspar closure for the NE sample. The inflection to a slower rate of cooling for the NE quartz monzonite while rapid cooling continued in the SW (Fig. 28) suggests motion probably stopped on this fault, and extension changed to down-to-the-west on a separate fault. Flexural rotation and isostatic rebound of the footwall of this second fault during exhumation (Buck, 1988) may explain the change in cooling rate across the Granite Mountains that was recorded in the K-feldspars (Fig. 33). The isostatic response of the footwall may result in an increase in exhumation rate and accommodate the narrow interval between initial K-feldspar closure between the SW monzogranite and central granodiorite samples (Figs. 28 and 30). Footwall refrigeration due to displacement along this fault would only effect the SW and central Granite Mountains samples, as the NE sample would be >10 km from the fault. Motion on this fault may have lasted until ~66 Ma, when NE K-feldspar ceased recording (Figs. 28 and 30). Following exhumation along this top-to-the-southwest normal fault, the Granite Mountains samples were likely in the upper 5 km of the crust where they remained while slow erosional denudation proceeded through the Oligocene.

Figures 32 and 33 summarize this conjugate fault model for the exhumation of Granite Mountains plutons. Faults are north-to northwest striking dipping outward from the Granite Mountains at angles of 65 ° in the NE and 30 ° in the SW. The steeply dipping fault in the NE is proposed to accommodate a significant amount of displacement to juxtapose the Granite Mountains and southern Providence Mountains. Whereas a

Figure 31. Cooling paths created by numerical normal fault modeling (solid black lines) are in agreement with reconstructed thermal histories based on thermochronology. The model cooling paths correspond to the fault model shown in figure 33.

Figure 32. Two-dimensional numerical model for cooling of rocks during normal faulting. a. Initial sample positions based on geobarometry and map distance with a 30 °/km geothermal gradient. Fault is dipping 65° northeast. b. Post faulting positioning of samples with compressed geotherms. Fault was modelled from 76 to 74 Ma with a slip rate of 3.5 mm/yr. This event may explain juxtaposition of the mid-crustal Granite Mountains next to the shallow-crustal southern Providence Mountains.

Figure 32.

Figure 33. Schematic of SW dipping detachment fault. a. Samples are in positions following exhumation along the NE fault. At ~74 Ma motion ceases on the NE fault and begins on the SW fault. b and c. Samples are exhumed along the SW fault. d. Following removal of the upper plate, the footwall rebounds isostatically accounting for the increase in exhumation rate and rapid cooling recorded in the SW and central K-feldspar samples. The fault trace at the surface is proposed to be far enough to the SW so that the NE and Providence Mountains samples decrease in cooling rate and are not affected by the isostatic response of footwall unroofing.

reverse fault with a similar geometry to the modeled NE normal fault would also accommodate initial cooling and juxtaposition of the two complexes, the regional extensional tectonism that is related both spatially and temporally to the data in this study suggests extensional faulting is a more likely explanation. The SW dipping fault accommodated more extension than the NE fault with a shallower dip (?), a longer interval of activity, and more rapid cooling indicating faster exhumation.

For Late Cretaceous Granite Mountains plutons, intrusion and extensional tectonics appear to be temporally related. Relationships between magmatism and extensional deformation have been suggested in the formation of many metamorphic core complexes (Hill et al., 1995; Walker et al., 1995; Foster and Fanning, 1997). Igneous intrusions have been proposed to provide a heat source to thermally weaken overlying crust and trigger rock failure, i.e. detachment faulting, which exhumes the metamorphic core complex. Although the Granite Mountains may not represent a metamorphic core complex (any structures that may have existed have been removed by erosion), they are similar in that they represent mid-crustal rocks emplaced in the shallow crust due to (most likely) low angle detachment faulting. The syntectonic intrusion of Granite Mountains plutons, indicated by reconstructed thermal histories, suggests magmatism may have been a driving force in initiating extensional faulting.

Exhumation dominantly by a top-to-the-southwest low angle fault is consistent with Late Cretaceous low-angle shear zones in the region. Foliations in the Pinto shear zone in the New York Mountains (Fig. 3) dip 20 to 65° south and southwest with top to the SW motion and was active from ~71 to 65 Ma (Beyene et al., 2000). This interval of tectonic activity is synchronous with the time intervals recorded in K-feldspar from the

SW monzogranite and the central granodiorite. The proximity of this shear zone (~65–70 km) to the Granite Mountains and the similarity of K-feldspar models suggest a possible link to the same top-to-the-southwest extensional structure. Motion on a low-angle top-to-the-southwest shear zone also occurred ~65 km to the southwest of the Granite Mountains in the Old Woman Mountains (Fig. 3) during the interval 73 to 68 Ma (Foster et al., 1989). Extension occurring at 72 to 70 Ma in the Funeral Mountains of Death Valley was also accommodated by a low-angle west dipping shear zone (Applegate et al., 1992; Hodges and Walker, 1992). The East Providence fault zone, although steeply dipping, was also a down-to-the-west structure active at ~70 Ma. Rapid cooling recorded in K-feldspars from Granite Mountains plutons from 71 to 66 Ma (Fig. 20) further supports regional top-to-the-southwest extensional deformation in this part of the southern Sevier belt.

Implications from U-Th/He ages

Apatite U-Th/He ages indicate a period of very slow cooling through 70 °C from the Late Cretaceous to the Tertiary (Fig. 24–27). Ages range from 40 to 21 Ma and are correlative with elevation (Fig. 18). The central granodiorite pluton has the highest elevation and the oldest age and was therefore cooled through 70 °C by erosional denudation first, followed by samples at lower elevations.

Although at least one fault separates the syenogranite pluton in the southern Providence Mountains from the Granite Mountains, the apatite age fits within the overall age-elevation correlation (Fig. 18). This suggests a period of tectonic quiescence and slow cooling from ~40 to 21 Ma during which the Granite Mountains and southern

Providence Mountains were exhumed as a single block during slow erosional denudation. Therefore, motion on the Granite Pass fault, which separates the Providence and Granite Mountains and may be a remnant of the proposed NE fault in this study, likely occurred pre-Oligocene. The apatite ages indicate the plutons were near the upper 2 km of the crust prior to the onset of Basin and Range extension (~25 Ma), which may have supplied the final movement upward through He closure temperature (70 °C) for the lower elevation samples.

U-Th/He data may also help to constrain timing of faulting within the Granite Mountains. The NE quartz monzonite pluton is separated from the other Granite Mountains plutons by a north-northwest striking down-to-the-northeast normal fault (Howard et al., 1987; Miller et al., 1991) (Fig. 2). If the age-elevation correlation is indicative of slow cooling through 70 °C as a single tectonic block, movement on this fault must have occurred pre-Oligocene. Although this is a short fault suggesting minimal displacement, U-Th/He ages are sensitive to as little as ~100 m (Fig. 18) indicating any significant movement on the fault likely predated passage through the He closure temperature. If the pluton were down dropped subsequent to cooling through 70 °C, an older age (such as that of the central granodiorite or Providence syenogranite) would have been recorded. No crystal size to age correlation exists in the apatite data, which further supports the age relationships to be structurally controlled, and suggests this fault may be Cretaceous.

Information on erosion rates may also be inferred from apatite ages. Figure 34 is a plot of paleodepth/ temperature vs. age at 40 Ma, when the central granodiorite cooled through 70 °C. Paleodepths are inferred from the present sample elevations and

Figure 34. Paleodepth vs. age plot for Granite and Southern Providence Mountains samples (boxes). Sample elevations are reflected as paleodepth with respective temperature based on 30 °C/km geothermal gradient at 40 Ma when the central granodiorite cooled through 70 °C. Exhumation rates due to erosional denudation are shown for each interval between samples. Plot indicates erosion rates decreased between 40 and 20 Ma.

temperatures are based on 30 °C/km geothermal gradient. Erosion rates can be determined based on the difference in depth and timing of He closure between each sample. These data indicate that erosion rates decreased from 0.09 mm/yr at ~40 Ma to 0.005 mm/yr at ~20 Ma.

Relations between the Granite and southern Providence Mountains

One goal of this project was to determine if there was a structural or tectonic relationship between the Granite Mountains and the southern Providence Mountains. Any model must explain geobarometry data, which indicate that the Granite Mountains plutons were emplaced at similar mid-crustal depths whereas the southern Providence Mountains plutons were emplaced at shallow depths. One hypothesis of this study was that the two mountains ranges might represent a single crustal section exposed at the surface due to tilting during extension. Geobarometry results showing similar emplacement depths for the three Granite Mountains plutons rather than (significantly) progressively deeper depths to the southwest (reflecting surface distance between samples) do not support a tilted a crustal section.

The tectonic model in figures 32 and 33 provides a more consistent explanation for the data, and suggests the Granite Mountains plutons were emplaced at crustal levels deeper than the southern Providence Mountains plutons. Their present-day juxtaposition can be explained as a single crustal section cut by a normal fault during extensional tectonism, which placed deep and shallow segments adjacent to each other at the surface.

The geobarometry for the syenogranite in the southern Providence Mountains (Fig. 27) indicates that the pluton was quickly cooled as a result of emplacement into cool

shallow crustal rocks. By 75 Ma the pluton had probably cooled below $\sim 200^{\circ}\text{C}$, whereas the Granite Mountains plutons were just being emplaced. Following reheating, the southern Providence Mountains likely underwent slow cooling similar in rate to the interval from ~ 66 to ~ 20 Ma in the Granite Mountains. This implies that Late Cretaceous exhumation juxtaposed the deeper-seated Granite Mountains and shallow southern Providence Mountains and the two experienced slow erosional cooling as a single block during a period of Early Tertiary tectonic quiescence.

Extensional collapse of the Sevier Orogen

Extensional collapse of overthickened crust during mountain building events is a well-known phenomenon that has been documented in ancient as well as the active orogens such as the Himalayan orogen. A significant body of evidence indicates widespread extensional tectonics occurred during the Late Cretaceous within the Sevier orogen as a result of gravity-driven collapse of overthickened crust.

Hodges and Walker (1992) suggest that mid-crustal detachment faults and decollements accommodated extension in the Sevier hinterland. Motion on low-angle normal faults in the Raft River Mountains (Utah) and Black Pine Mountains (Idaho) has been constrained between ~ 100 and 82 Ma based on $^{40}\text{Ar}/^{39}\text{Ar}$ muscovite ages (Wells et al., 1990). The Mahogany Peaks fault, juxtaposing Ordovician and Proterozoic rocks in the Raft River Mountains is interpreted as a low-angle top-to-the-west normal fault active in the Latest Cretaceous to Paleocene (90 to 47 Ma) and possibly synchronous with $^{40}\text{Ar}/^{39}\text{Ar}$ ages for cooling of the footwall (~ 70 to 60 Ma) (Wells et al., 1998). These support low angle extensional tectonics in the central regions of the Sevier hinterland.

In southeast California, low angle shear zones and detachment faults dominate the Late Cretaceous extensional structures supporting Sevier orogenic collapse (Hodges and Walker, 1992). Rapid cooling of plutonic rocks in the Old Woman Mountains (Fig. 3) was accommodated along a west dipping, normal sense, ductile shear zone active from 73 to 68 Ma (Carl et al., 1991; Foster et al., 1992). Miller et al. (1996) correlated three down to the west extensional structures to postulate the East Mojave Fault. This fault zone extends mainly north south and is defined by the Cima fault zone, Pinto Shear zone, and East Providence fault zone. Mylonite in the Cima fault zone suggests normal, down to the west shear active in the Late Cretaceous based on cross cutting relationships (Miller et al., 1996). The Pinto shear zone is a shallow dipping (20 to 65°) down to the west normal sense shear zone in the New York Mountains (Fig. 3) that was active from 71 to 65 Ma (Beyene et al., 2000). Motion on the East Providence fault zone took place between the latest Cretaceous and early Miocene based on cross cutting relationships with 76 to 80 Ma dikes and the Miocene Wildhorse Mesa tuff (Miller et al., 1996). The East Mojave Fault may represent a link between southern extension in the Old Woman Mountains and extension in the Funeral Mountains of Death Valley (Fig. 3) where top the southwest shearing was occurring at 72 Ma, lasting until 70 Ma (Applegate et al., 1992).

The Granite Mountains are located west of the postulated East Mojave Fault. Rapid cooling of Granite Mountains plutons at ~76 to 66 Ma correlates very well with the timing of rapid cooling in the surrounding Cretaceous extensional terrains. Exhumation dominated by a top to the southwest low angle normal fault is consistent with surrounding extensional structures, especially the nearby Pinto Shear zone (71 to 65 Ma) with K-feldspar models almost identical to the central and SW Granite Mountains plutons

(~71 to 67 Ma). The matching time intervals recorded in K-feldspars along with the close proximity (~50 to 60 km) of the Granite Mountains and Pinto Shear zone may be indicative of a single large-scale Late Cretaceous extensional structure, which the postulated East Mojave Fault of Miller et al. (1996) may represent the central portion of. If so, this structure may be a single large-scale top-to-the-southwest extensional zone linking Late Cretaceous extensional structures from the Old Woman Mountains in the south to the Funeral Mountains in the north, accommodating gravitational collapse at the southern extent of the overthickened Sevier Orogen.

CHAPTER 9

CONCLUSIONS

Based on calibrations of the aluminum-in-hornblende geobarometer by Hollister et al. (1987) and Schmidt (1992), three Cretaceous plutons in the Granite Mountains intruded at pressures of 4.0 to 4.8 kbar corresponding to mid-crustal depths of 14.5 to 17.1 km. A syenogranite pluton in the southern Providence Mountains intruded at 1.7 to 2.4 kbar suggesting shallow crustal emplacement levels of 7 to 9 km depth based on both geobarometry and $^{40}\text{Ar}/^{39}\text{Ar}$ thermochronology.

Emplacement of the Cretaceous plutons in the Granite Mountains was synchronous with Late Cretaceous extension during collapse of the overthickened Sevier Orogen beginning at ~75 Ma. The syenogranite pluton in the southern Providence Mountains was emplaced in the Jurassic at 151 ± 8 Ma as part of earlier extensive arc magmatism throughout the Cordillera.

Rapid cooling of Granite Mountains plutons through hornblende closure (~500 °C) was likely a result of conductive heat loss due to mid-crustal emplacement. Continued rapid cooling can be explained by short-lived (76 to 74 Ma) movement along a top-to-the-NE normal fault juxtaposing these plutons against cooler shallow crustal rocks in the neighboring southern Providence Mountains. Numerical models indicate a fault dipping 65 ° NE with a slip rate of 3.5 mm/yr from 76 to 74 Ma will reproduce the high temperature (~500-300 °C) interval of the reconstructed thermal histories and may

accommodate this juxtaposition. K-feldspar models suggest cooling rates of 63 to 16 °C/Ma from southwest to northeast in the Granite Mountains. This cooling interval (~73 to 66 Ma) was probably accommodated by a top-to-the-southwest normal fault to the southwest of the Granite Mountains, which would be the dominant structure in the exhumation of the plutons. Flexural rotation with isostatic rebound of the footwall during faulting and possibly an increase in exhumation rate may explain the change in cooling rate from SW to NE. It is likely that exhumation dominated by the top-to-the-west fault was similar to unroofing in many metamorphic core complexes where syntectonic plutons provide a heat source to thermally weaken overlying rocks and initiate detachment faulting. This rapid cooling event coincides temporally and spatially with the nearby top-to-the-southwest Pinto Shear zone, which was active from 71 to 65 Ma relating the Granite Mountains to a possible single large scale extensional structure in the Mojave Desert region.

U-Th/He apatite ages indicate that following rapid Late Cretaceous exhumation, Granite Mountains plutons underwent slow cooling lasting through the Oligocene. The southern Providence Mountains also underwent similar slow cooling from Late Cretaceous to ~35 Ma, indicating juxtaposition of the Granite Mountains and southern Providence Mountains occurred during Late Cretaceous extensional tectonics. Apatite ages also indicate the plutons were in the upper crust prior to Basin and Range extension, which may have contributed to their final movement upward.

APPENDIX A

Sample Descriptions

Calvin: 34° 46' 34.8" N, 115° 44' 26.4" W

Calvin was collected in the southwest Granite Mountains from a pluton mapped as Cretaceous porphyritic monzogranite (Kpm) (Miller et al., 1985) (Fig. 2). This unit is known as the Granite of Arrowweed in the southern Providence Mountains (Miller et al., 1985). This pluton makes up the southern half of the range and is the largest pluton found in the Granite Mountains. The granite is coarsely crystalline (~2-3 mm), containing K-feldspar phenocrysts and large biotite crystals in hand sample. Plagioclase, quartz, K-feldspar, biotite, and hornblende are all widely present in thin section. Sphene and apatite are also abundant with zircons commonly found as inclusions within biotite.

Floyd: 34° 48' 51.0" N, 115° 41' 40.2"W

Floyd was collected from a Cretaceous granodiorite (Kgd) (Miller et al., 1985) near the center of the Granite Mountains. This unit is exposed in the interior of the range and also in the southwest (Fig. 2) and may be described as an equigranular hornblende-biotite granodiorite (~1-2 mm). Thin section shows quartz, plagioclase, K-feldspar, and abundant hornblende and biotite. Zircon is present as inclusions within biotite and there is also apatite and large sphene crystals.

Yoshi: 34° 49' 58.0" N, 115° 39' 11.5" W

Yoshi was taken from a pluton in the northeast Granite Mountains described by Miller et al. (1985) as a Jurassic spotted quartz monzonite (Fig. 2). The sample has a visible fabric, which has been determined as magmatic (boundary flow) rather than metamorphic due to a lack of prominent foliation and metamorphic minerals in thin section. The sample is a medium to fine-grained (~1-2 mm with large ~3-5 mm mafic clots) hornblende-biotite quartz monzonite (Miller et al., 1985). Thin section shows abundant plagioclase with quartz and K-feldspar. Sample is also rich in biotite and hornblende, zircon common as inclusions and scattered apatite.

Omar: 34° 52' 11.7" N, 115° 34' 52.1" W

Omar was collected in the southern Providence Mountains from the Jurassic quartz monzonite of Goldstone (Miller et al., 1985) (Fig. 2). The hand sample is darker in color than those from the Granite Mountains and is medium to coarse grained (~1-3 mm). The mafic phases appear as clusters. Thin section shows plagioclase, quartz and K-feldspar with large biotite and hornblende with pyroxene (?). Apatite and zircon are scattered throughout with zircon common as inclusions in biotite.

APPENDIX B

Electron Microprobe hornblende chemical analyses

Appendix B consists of the standards used for calibration along with chemical data for Kakanui Hornblende, which was the standard, used during analyses. Data tables of hornblende chemical analyses are listed in sequence from a to e representing rim-to-core-to-rim analyses where a and e are rims and c is core. SEM images of hornblendes with respective spots analyzed are also included.

Standards used in calibration

Analysis	Lab Number	Supplier	Mineral Name	Standard Number
Al₂O₃	UNLV-44	Harvard	Green's Creek Almandine	HMM 112140
FeO	UNLV-45	Harvard	Green's Creek Almandine	HMM 112141
K₂O	UNLV-49	USNM(1)	Microcline	USNM 143966
Na₂O	UNLV-76	MAC-EMS	Jadeite

**Graduate College
University of Nevada, Las Vegas**

Joseph Louis Kula

Local Address:

**1551 Lorilyn Ave. #1
Las Vegas, NV 89119**

Home Address:

**123 Hawthorne Ave.
Nutley, NJ 07110**

Degrees:

**Bachelor of Science, Geoscience, 2000
Montclair State University, NJ**

**Master of Science, Geoscience, 2002
University of Nevada, Las Vegas**

Special Honors and Awards:

**UNLV Graduate Student Association Research Grant, Fall 2002
UNLV GREAT Scholarship, Summer 2002
UNLV Geoscience Department Research Grant, Spring 2002
Phi Kappa Phi Honors Society, 2001-2002
UNLV Graduate Student Association Research Grant, Fall 2001
UNLV Graduate Student Association Research Grant, Spring 2001
UNLV Geoscience Department Research Grant, Spring 2001
Arizona Nevada Academy of Science Research Grant, Spring 2001**
