## **Abstract**

Recognizing how rifts develop through space and time is vital to enrich our understanding of continental breakup. Rifts are commonly segmented by transfer or accommodations zones that form as the rift develops due to differences in the onset, direction, magnitude, or rates of extension on either side of the transfer or accommodation zone. The Basin and Range province is a wide rift where Cenozoic extension overprints and exposes earlier Mesozoic Sevier fold-thrust belt shortening structures. This exposure allows Sevier thrust correlations between individual mountain ranges and use of these shortening structures to study rift segmentation by strike-slip transfer faults. The purpose of this study is to further develop our understanding of regional tectonism by unraveling the tectonic history of the Kane Springs Wash area, Nevada, from Sevier shortening and hinterland highland development, through highland erosion, and finally to overprinting by Miocene-Quaternary strike-slip and normal faults associated with rift segmentation. Focus is placed on clarifying (1) long term issues in the reconstruction of Sevier-related thrusts and the former Sevier hinterland; and (2) the development of a boundary zone within the Basin and Range province that contains strike-slip faults and whether it may be a rift segment boundary. Sevier thrusts exposed in the Delamar and Meadow Valley mountains are offset by a major Cenozoic left-lateral fault, the Kane Springs Wash fault that lies at the southern reach of the boundary zone between the Northern and Central Basin and Range subprovinces. This boundary zone is spatially coincident with the southern Nevada seismic belt where distinct changes in topography, style of deformation, rock exposures, and gravity anomalies occur/ These changes and the structures, together, suggest that the zone may operate as a rift segment boundary.

Using new geologic mapping, detrital zircon ages, and structural analyses, I illustrate several key findings. (1) The left-lateral Kane Springs Wash fault is a transfer fault that separates two distinct domains of extension on either side. (2) The Kane Springs Wash fault zone lies at the southern reach of the boundary zone between the Northern and Central Basin and Range subprovinces, helping to accommodate differences in slip across the broad boundary zone in conjunction with other ~E-W striking structures. (3) The newly dated Eocene conglomeratic sediments, ~39 Ma, that overlie Sevier-related thrusts, show that the earlier Sevier hinterland highland lies to the North and West of the Kane Springs Wash area. (4) The Delamar and Meadow Valley thrusts are distinct faults and the Dry Lake thrust is the southward lateral equivalent of the Delamar thrust. That correlation provides southward continuity to a major regional thrust sheet and requires it to be placed in regional reconstructions where it has rarely been included.

Two major findings are drawn from this work. (1) The classification of the NBR-CBR boundary zone as a segment boundary within the Basin and Range is novel yet needed to better understand how the rift developed through time. (2) The southward correlation of the Delamar-Wah-Wah system to the Dry Lake system is new and furthers our understanding of the architecture of the Sevier retroarc-fold-thrust-belt particularly because this large thrust system has been inappropriately minimized in regional reconstructions.

## **Acknowledgements**

This document is dedicated:

To my advisor, Wanda J. Taylor, without whom I would never have been able to do any of this.

To my thesis committee, who provided valuable time, thoughts and input.

I also want to extend thanks to the Clark County Building Department for funding portions of my research through a grant to C.M. dePolo and W.J. Taylor.

To all those that helped in completing this research. The long days of fieldwork were worth it all the more because you were there.

To all the wonderful friends I have met along the way! Without you none of this would be bearable.

To anyone who ever doubted my capacity to do anything worthwhile. I perhaps owe you the most.

Thank you all.

## **1. Introduction**

Overprinted or superposed deformations commonly modify the geometry of earlier structures, providing research opportunities because those early structures may become exposed and can be used to analyze the younger structures. Consequently, despite the tendency for structural geometries to be complex in areas of overprinted deformation, these areas provide valuable insights into each deformation individually and deformation through time. A prime example of an area of overprinted deformation is the Basin and Range province (BRP) where Cenozoic extensional structures overprint a variety of ages of shortening structures (Figs. 1, 2; Wernicke et al. 1988; Snow and Wernicke, 2000; Taylor et al., 2000; Friedrich and Bartley; 2003; DeCelles, 2004; Bidgoli, 2005; Dickinson, 2006; Long 2012; Greene, 2014).

A fundamental aspect of rifts, like the BRP, is that they are commonly segmented by strike-slip faults and/or by dip-slip fault terminations in transfer and accommodation zones that strike at high-angles to the tectonic and structural grain of the rift (Faulds and Varga, 1998; Rowley, 1998; Thenhaus and Barnhard, 1998; Pérouse and Wernicke, 2017). Transfer and accommodation zones can be discrete and spatially limited or broad with a much greater spatial extent (Faulds and Varga, 1998; Rowley, 1998; Thenhaus and Barnhard, 1998; Pérouse and Wernicke, 2017). These zones form as the rift develops and are generated by differences in timing of onset, direction, magnitude, or rates of extension along the length of the rift, transmitting slip from either side and linking the rift segments (Faulds and Varga, 1998; Rowley, 1998; Thenhaus and Barnhard, 1998; Pérouse and Wernicke, 2017). The BRP can be divided subprovinces that may represent different rift segments (e.g., Bidgoli, 2005): the Northwestern, Northern (NBR), Central (CBR), and Southern Basin and Range subprovinces (Fig. 3). The onset of extension within the CBR is younger, has a different magnitude and a higher rate of extension

than that of the Northern and Southern Basin and Range. A major BRP boundary that lies between the NBR and CBR subprovinces (Fig. 3) is considered in this study in light of general rift segmentation concepts.

Decades of work in the BRP on areas that are structurally complex due to extensional deformation overprinting shortening structures draws attention to several important problems that remain unsolved (Tschanz and Pampeyan, 1970; Pampeyan, 1993; Swadley et al., 1994; Snow and Wernicke, 2000; Friedrich and Bartley, 2003; Cassel et al., 2018; Giallorenzo et al., 2018). Regarding Cenozoic extension, the youngest deformation in the BRP, an important issue is the kinematic and regional tectonic role of many E-W to NE-SW-striking structures that cut across the primary structural grain of the BRP and their relation to other local and regional structures. Is the NBR-CBR subprovince boundary zone, a rift segment boundary, how does the ~NE-striking KSW fault zone relate to the segmentation of the BRP as a whole (Figs. 3, 4)?

What are the accurate geometries and histories of faults that segment the BRP and do they act as slip transfer zones between the NBR and CBR subprovinces? Because rift segment boundary zones contain different structures and have different structural and earthquake histories than the surrounding rift segments, documenting them is critical to developing structural and regional tectonic models. In parts of the BRP, the Cenozoic structures overprint the Jurassic to Eocene retroarc Sevier fold-thrust belt and the associated hinterland highland or plateau (Figs. 1, 2, 5; Plate 1). Additional structural issues surround that older deformation. The following are addressed here. (1) What are the structural geometries and styles where extensional structures overprinted and disrupted the geometry and configuration of the Sevier fold-thrust belt and the Sevier hinterland at the southern edge of the NBR-CBR boundary zone? (2) What are the distinguishing characteristics of the DT and MVT thrusts of the Sevier fold-thrust belt and how

do they relate to other regionally important Sevier-related structures? This information is used to determine structural style and correlate thrusts along strike as well as to ascertain the location of the Sevier hinterland within space and time. (3) What process(es), tectonic or erosional denudation, resulted in the demise of the Sevier hinterland highland and where do the DT and MVT sit in relation to the Sevier hinterland highland? When did the processes that resulted in the demise of the Sevier hinterland highland occur? The magnitude and configuration of the paleorelief present in the time interval between Sevier orogenesis and extension reflects on thrust geometry as well as depositional systems.

This work addresses these issues in an understudied area with substantial structural overprinting, the Kane Springs Wash (KSW) area, southern Nevada, where Miocene-Quaternary strike-slip and normal faults overprint older Sevier-related shortening structures (Figs. 1, 2; Plate 1 – Appendix A). This area supplies an opportunity to use older Sevier structures to study younger extensional structures and vice versa. The Sevier thrusts are chiefly the Delamar (DT) and Meadow Valley (MVT) thrusts, located in the Delmar and Meadow Valley mountains. The major Cenozoic structure is the KSW fault zone which is ~41 km long and has apparent left-lateral offset estimates ranging between ~8 and 12 km (Anderson, 1999). The KSW area also provides an opportunity to study the evolution of a major Sevier thrust system and the breakdown of the Sevier hinterland highland at a latitude where the hinterland and frontal thrusts diverge to the north. This case study allows us to address these issues and apply the information gleaned to the BRP province and Sevier fold-thrust belt in a broader context.

I use new field mapping, structural analyses, and detrital zircon maximum depositional ages and provenance data to track the evolution in the KSW area from Sevier thrusts and hinterland highland development through demise of the highland and finally to the overprinting of thrusts

by Miocene-Quaternary extension with strike-slip and normal faults involved in developing rift segmentation. From these analyses, I suggest the following. (1) The KSW fault zone operates as a Miocene and Quaternary transfer zone between two domains of extension, here called the NW and SE domains, which have differing extensional styles, distribution and magnitudes on either side of the KSW fault zone. In addition, the KSW fault zone forms part of the southern limit of the NBR-CBR boundary zone, which is considered a rift segment boundary dominated by left-lateral transfer faults. (2) The location of part of the eastern slope of the Sevier hinterland highland lies in and near the KSW area. (3) A major thrust, the Delamar thrust (DT), continues southward and correlates with the Dry Lake thrust. This correlation suggests a larger regional distribution of this structure that is often overlooked in reconstructions of the Sevier retroarc fold-thrust belt at the latitude of southern Nevada.

## **2. Tectonic and Depositional Settings**

Six broad groups of rocks and periods of tectonism are relevant to this study: (1) early Paleozoic, carbonate-dominated passive margin sedimentation disrupted during the Antler orogeny; (2) mid to late Paleozoic tectonism from the Antler through the Sonoma orogenies, with intervening tectonic events and the dominantly shallow marine sedimentary rocks deposited during that time interval; (3) Sevier orogenesis associated with subduction of the Farallon plate and sedimentation in piggyback and foreland basins; (4) post-Sevier but pre-Oligocene volcanic and sedimentary deposition – chiefly, the local Eocene conglomeratic sediments (Ecs); (5) Oligocene to Miocene extension, including strike-slip faulting, and ash-flow tuff emplacement attributed to the ignimbrite flare-up associated with roll-back of the Farallon slab; and (6) lastly, the late Pliocene(?) to Quaternary extension with basin-fill deposits and alluvium deposited into the lows created by the faults.

### ***Early to Late Paleozoic History***

In the southwestern U.S., the early to late Paleozoic is dominated by passive margin sedimentation along the western Laurentia margin (Dickinson, 2004; Dickinson, 2006; Yonkee and Weil, 2015). This period of passive margin sedimentation leads to the development of a sedimentary prism dominated by marine carbonates. This westward thickening sedimentary wedge was draped atop basement rocks from the Mojave, Yavapai, Mazatzal, and Wyoming provinces as well as the Farmington zone and the Grouse Creek block (Dickinson, 2004; Dickinson, 2006; Yonkee and Weil, 2015). The KSW area lies approximately within a thinner portion of the sedimentary prism. The area lies E of the initial  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio 0.706 line on continental crust and in the region of shallow and relatively thin deposits (Figs. 1, 2; Wooden et al., 1998; Yonkee and Weil, 2015). The units of this sedimentary prism typically make up the

Sevier thrust plates exposed in the KSW area (Yonkee and Weil, 2015; Swanson and Wernicke, 2017).

The middle to lower Cambrian up into Devonian rocks exposed within the study area range from the passive margin carbonate-dominated Cambrian Highland Peak Formation to Devonian Guilmette Formation (Fig. 6; Plate 1; Longwell, et al., 1965; Tschanz and Pampeyan, 1970; Pampeyan, 1993; Scott et al., 1995; Swanson and Wernicke, 2017). The lateral equivalent of the Cambrian Highland Peak Formation is the Cambrian Bonanza King Formation that commonly occurs in the upper plate of Sevier belt thrusts such as the Keystone thrust (Figs. 1, 2, 6; Longwell, et al., 1965; Tschanz and Pampeyan, 1970; Burchfiel et al., 1982; Long, 2012). The Ordovician Pogonip Group, Ordovician Eureka Quartzite, Ordovician Ely Springs Dolomite and Silurian Laketown Dolomite are not exposed in the thinner cratonal sections east of the Sevier front further demonstrating passive margin sedimentation at the time of deposition (e.g., Tschanz and Pampeyan, 1970; Garrity and Soller, 2009).

During late Devonian to early Triassic time the southwestern Laurentian margin underwent a series of events with southeastward-directed shortening and transpression along generally NE-SW trending structures, oblique to the western Laurentian margin, with synconvergent sedimentation in foreland and successor basins (Cashman et al., 2000; Lawton et al., 2017).

Consequently, the passive margin sedimentation was replaced by shallow marine deposition in new foreland and successor basins associated with the Antler and Sonoma orogenies and the intervening Late Paleozoic transpressive deformation (Cashman et al., 2000; Dickinson, 2004; Dickinson, 2006; Lawton et al., 2017; Yonkee and Weil, 2017; Sturmer et al. 2018). This deformation occurred northwest of the study area but influenced the basins and sedimentation within the KSW area, particularly the late Mississippian to early Permian Bird Spring Formation

which typically occurs in the lower plate of the DT and MVT (Sturmer et al., 2018; Cashman and Sturmer, 2021).

### ***Mesozoic History***

The Sevier retroarc fold-and-thrust belt and its hinterland highland developed in the late Jurassic to mid-Cretaceous and into the Eocene, in the north, in response to the subduction of the Farallon oceanic plate eastward underneath western Laurentia (DeCelles, 2004; Dickinson, 2004; DeCelles et al., 2006; Dickinson, 2006; Busby and Putrika, 2009; Greene, 2014, Yonkee and Weil, 2015; Cassel et al., 2018; Giallorenzo et al., 2018). The Sevier hinterland highland has modest internal relief, locally documented in this study, and is commonly called the Nevadaplano (DeCelles, 2004; DeCelles et al., 2006; Druschke et al., 2011; Long, 2012; Greene, 2014; Long, et al., 2015; Erdman, et al., 2016). This highland reached elevations that may have been as much as ~8 km or greater, but more likely was 2-3 km high (DeCelles, 2004; DeCelles et al., 2006; Long, 2012; Snell, et al., 2014; Long, et al., 2015; Erdman, et al., 2016). The highland contained that regional topographic maximum and included a major ~N-S drainage divide in the Intermountain West during its lifetime (Figs. 1, 2; DeCelles et al., 2004; Henry and Faulds, 2010; Long, 2012; Henry et al., 2012; Best et al., 2013b; Snell et al., 2014; Long et al., 2015). The Cordilleran magmatic arc and accreted terrains at the western margin of Laurentia developed from mid-Triassic to mid-Jurassic time also in response to subduction of the Farallon plate (Dickinson, 2004; Dickinson, 2006; Greene, 2014; DeCelles and Graham, 2015; Yonkee and Weil, 2015). The KSW area sits E of the Cordilleran magmatic arc and W of the Sevier frontal thrusts, within the Sevier retroarc fold-thrust belt where drainage would be eastward off the highland.

Several regional structures are important to understanding the spatial extent of the former Sevier hinterland and the role the KSW fault plays in later deformation. Important and well-known thrusts include the Gass Peak thrust, Valley thrust, Dry Lake thrust, and the Muddy Mountain-Mormon thrust (Keystone thrust correlatives), from structurally highest to structurally lowest. These thrusts are exposed near the map area and must be considered relative to the DT and MVT in the KSW area. Those thrusts, their along-strike correlatives, and the typical stratigraphic separation in the Spring Mountains, and Sheep and Las Vegas ranges area are as follows (Fig. 1). The Gass Peak-Wheeler Pass thrust system is correlative to faults and folds in the central Nevada thrust belt and places Late Precambrian and Cambrian rocks atop Pennsylvanian-Permian footwall rocks in the south with decreasing stratigraphic separation northward (Taylor et al., 2000; Long, 2012; Giallorenzo et al., 2018). Structurally below that thrust system, the Lee Canyon thrust places Cambrian Bonanza King and Nopah formations atop Pennsylvanian and Permian rock in its footwall (Burchfiel et al., 1974; Lundstrom et al., 1998; Pavlis et al., 2014). The Lee Canyon and Deer Creek thrusts, together, have differing northward along-strike correlatives in different interpretations; one suggested correlative is the Valley thrust and another is the Dry Lake thrust (Pavlis et al., 2014). The Valley thrust lies in the footwall of the Gass Peak thrust and places Pennsylvanian-Permian rock atop Pennsylvanian-Permian rock in its footwall, which is inconsistent with the Lee Canyon thrust (Lundstrom et al., 1998; Page et al., 2005). The Dry Lake thrust place Cambrian and Devonian rock atop the Pennsylvanian-Permian Bird Spring Formation.

During late Cretaceous time, in response to flattening of the Farallon slab dip, the arc migrated eastward, the eastern Sevier retroarc thrusts were active, and basement-cored uplifts initiated and continued to develop in the foreland until ~50 Ma (DeCelles, et al., 2004; Dickinson, 2004;

Dickinson, 2006; Yonkee and Weil, 2015; Best et al., 2016). This switch to a flat-slab style of subduction is coupled with the inboard migration of both arc magmatism and the initiation of basement-cored uplifts to the east of the Sevier belt, called the Laramide orogeny (Dickinson, 2004; Dickinson, 2006; Best et al., 2009; Smith et al., 2014; Best et al., 2016; Yonkee and Weil, 2015). Farallon flat-slab subduction lasted from the latest Cretaceous until slab foundering and rollback primarily during Eocene to Miocene time (Dickinson, 2004; Dickinson, 2006; Best et al., 2009; Smith et al., 2014; Best et al., 2016; Yonkee and Weil, 2015).

### ***Eocene History***

Near KSW and the surrounding areas, a period of relative tectonic quiescence occurred from ~40 until ~23 Ma during which the former Sevier hinterland remained a prominent topographic high (DeCelles et al., 2004; Cassel et al., 2014; Best et al., 2016). This hinterland highland or plateau was suggested to be destroyed through various means such as gravitational collapse and erosional denudation (Cassel et al., 2018). Detritus from the Sevier hinterland was transported and deposited eastward and westward from a N-S drainage divide in central Nevada, leaving both lacustrine and fluvial sediments perched atop the hinterland plateau and Sevier thrusts at the base of the topographic slope from the divide to the east (Fig. 1; Henry, 2008; Henry and Faulds, 2010; Smith et al., 2017; Cassel et al., 2018). This erosional denudation, eastward off the hinterland, is of particular importance for the KSW area because it lies E of the former topographic maximum (Taylor et al., 2000; Long, 2012). Eastward erosional denudation off the hinterland plateau led to (1) the development of drainages that are now in disconnected exposures and (2) the deposition of alluvial, fluvial, and lacustrine sediments locally atop deformed Paleozoic and Mesozoic rocks of the Sevier frontal thrusts and foreland basins (Goldstrand, 1994; Henry et al., 2008; Greene, 2014; Smith et al., 2017; Cassel et al., 2018). This

time interval is represented within the KSW area by the Ecs (Eocene conglomeratic sediments) unit, previously mapped as TKc by Tschanz and Pampeyan (1970) and Tc and Tl by Swadley et al. (1994). The Ecs unit sits in a stratigraphic and structural position vital to unraveling the final configuration and paleogeomorphology of the Sevier belt and hinterland plateau after local shortening-related deformation has ended.

New observations indicate that Ecs comprises interbedded medium-coarse sandstone beds and conglomerate with pebble to large boulder-sized clasts, commonly capped by a fresh-water limestone. Graded bedding commonly is exposed throughout the conglomeratic sections. The section of graded beds is commonly capped by medium-fine to medium-coarse calcite cemented sandstone. The clasts are typically limestone, dolostone, and quartzite similar to rocks exposed in both the upper and lower plates of both the DT and the MVT as well as structurally higher plates such as the Gass Peak thrust plate. Although not exposed in all sections within the study area, calcite-cemented sandstone beds are typically deposited atop of a sequence of fining-upward carbonate and quartzite clast-dominated conglomeratic beds. In several locations, paleochannels are distinguished by cut-and-fill structures, but no distinct paleodrainage direction was definitively determined from clast imbrications or other paleoflow indicators.

The Ecs and similar deposits in the region previously were mapped as ranging in age anywhere from Cretaceous to Miocene; to restrict the age range, new detrital zircon provenance analysis was performed by T.S. Bidgoli (2020), on the Ecs unit in the KSW area. The new data suggest a maximum depositional age of ~39 Ma (Appendix B). Bidgoli's analysis indicates that detrital zircon grains within the Ecs unit are sourced primarily from Precambrian and Cambrian quartzites that are not exposed within the KSW area but are exposed in thrust plate structurally higher than the DT and MVT such as the Gass Peak thrust (Figs. 8, 9, 10, 11, Appendix B,

modified from T. Bidgoli; Longwell et al., 1965; Tschanz and Pampeyan, 1970; Page et al., 2005a, 2005b; Felger and Beard, 2010). Bidgoli notes that there are zircon grains from Ordovician quartzite but the unit lacks zircons from units such as the Devonian Oxyoke Canyon Sandstone and Mississippian Scotty Wash Quartzite, common to the upper plates of the local thrusts (DT and MVT). This provenance is a strong indication that a highland in the Sevier hinterland existed to the N and W of the KSW area before Cenozoic extension and drained generally east from ~39 Ma until its final demise by mid-Cenozoic and later extension and emplacement of tuffs by pyroclastic flows.

The rock types of the Ecs are consistent with alluvial or fluvial sedimentation that transitions to a lacustrine setting with the deposition of limestone. This sequence is typical for a drainage system off a proximal highland. I interpret the Ecs unit to represent the erosional denudation of a portion of the Sevier hinterland plateau across much of the orogenic wedge. In the Meadow Valley Mountains, the Ecs unit is composed of conglomerate and sandstone capped by a limestone unit that overlies or, completely composes the Ecs unit where former topography was high enough to preclude the lower clastic lithology. Exposures within the Delamar Mountains are composed of gravel to boulder-sized clasts weathering from beneath the tuffs with little to no limestone capping beds. The limestone generally thickens to the SE (Meadow Valley Mountains) where it is exposed in every section, while the lower conglomerate thins southeastward. This observation in conjunction with the detrital zircon analysis suggests that local drainage was to the south and east further supporting the interpretation that the former Sevier hinterland was a highland that laid to the west or northwest.

### ***Oligocene to Miocene History***

The Farallon slab began foundering at ~50 Ma in early Eocene time, supplying an influx of hot asthenospheric material to the lower crust and causing southwestward migrating pyroclastic volcanism – peaking from ~38 Ma in northern Nevada until ~18 Ma just north of the KSW area (Fig. 2; DeCelles, et al., 2004; Dickinson, 2006; Busby and Putrika, 2009; Best et al., 2013b; Best et al., 2016, Yonkee and Weil, 2015). This post-orogenic volcanism is called the ignimbrite flare-up (Best et al., 2016). In addition, plate reconstructions indicate that the southern part of the region of the ignimbrite flare-up, the CBR, may be influenced by a window in the Farallon slab that formed beneath the Mojave region during the 26-19 Ma time interval (Atwater and Stock, 2010). These reconstructions suggest that the early Miocene ignimbrite eruptions and extension in that area may be the result of asthenospheric upwelling into a sub-lithospheric slab window (Atwater and Stock, 2010). East of and across the former or remnant Sevier hinterland highland, the ignimbrites typically were erupted from caldera complexes (Figs. 1, 2; Busby and Putrika, 2009; Best et al., 2013, Best et al., 2016). Exposed within the KSW area are ash-flow tuffs erupted from both the Indian Peak and Caliente caldera complexes as well as the ~15 Ma KSW caldera (Longwell, et al., 1965; Tschanz and Pampeyan, 1970; Scott et al., 1994, Best et al., 2013). These rocks range in age from ~ 23 to ~15 Ma, but ash-flow tuffs as old as ~26 Ma may occur at depth at least in the NW domain of the KSW area (Figs. 6, 7; Plate 1; Best et al., 2013; Best et al., 2016). Paleomagnetic data across the KSW fault zone suggest that there has been no discernable vertical-axis rotation of the tuffs since deposition (Hudson et al., 1998). BRP extension as a result of NNE-striking faults and segmentation by ~E-W structures striking perpendicular to the primary tectonic grain as a whole are necessary to accommodate differences in the timing, magnitude and direction of extension within the NBR and CBR subprovinces (Wernicke et al., 1982; Wernicke, 1992; Dickinson, 2002; Colgan et al., 2006; Pérouse and

Wernicke, 2018; Long, 2019). Extension within the NBR began earlier in Oligocene to early Miocene time, whereas extension within the CBR began in middle Miocene time while extension continued in the NBR (Wernicke, 1992). Extension within the NBR is more west to west-northwest directed than the extension direction of west to west-southwest directed extension of the CBR (Wernicke, 1992). High magnitude extension associated with low-angle normal faulting – such as the Mormon Peak detachment – is greater and younger in the CBR than in the NBR (Figs. 1, 2, 3, 4; Wernicke, 1992). At the boundary between the NBR and CBR subprovinces strike-slip and transfer faults are noted with a slip history as early as Oligocene time (Abdelhaleem et al., 2020). These faults include faults of the Timpahute Lineament and Pahranaagat shear zone as well as the KSW fault zone (Figs. 1, 2, 3, 4).

#### ***Late Pliocene to Quaternary History***

By late Pliocene time, the modern Basin and Range physiographic province was marked by a lack of volcanism from the ignimbrite flare-up and little low-angle normal faulting as are typically associated with the earlier Cenozoic extension (Dickinson, 2004; Dickinson, 2006; Dickinson, 2010). At this time, the BRP deformation was generally E-W directed extension along high-angle, ~N-S-striking normal faults with basin fill sediments sitting atop hanging-wall blocks, generating the modern topography (Dickinson and Gehrels, 2010; Ellis et al., 2015). Quaternary faults in the northern and central BRP are generally NNE-striking and high-angle. Modern seismic studies combined with horizontal GPS measurements demonstrate that in the southern NBR and northern CBR subprovinces active deformation is focused along the eastern margin, the Intermountain Seismic belt; the western margin of the subprovince, which includes the Eastern California and Walker Lane seismic belts; and in the ENE-WSW trending southern Nevada seismic belt connecting the two rift shoulders (Kreemer et al., 2010). Major E-W to

ENE-WSW striking faults that lie within the southern Nevada seismic belt and spatially coincide with the NBR-CBR boundary zone are faults of the Timpahute Lineament, Pahrnagat shear zone, Caliente-Enterprise zone, and the KSW fault zone (Fig. 2; Tschanz and Pampeyan, 1970; Ekren, 1976; Axen, 1998; Hudson et al., 1998; Price, 2017; Ely and Taylor, 2018; Evans; 2018; Peck, 2018; Reed, 2019; Abdelhaleem et al., 2020; Reid et al., 2020; Taylor et al., 2022).

### **3. Methods**

I employed standard geologic mapping techniques using both a GPS enabled tablet with the software FieldMOVE and a Brunton geologic compass to collect attitudes of bedding, compaction foliations, faults, and folds to generate a highly accurate geologic map at a scale of 1:24000 of the KSW area. Measurements and data collected via mapping and NAIP (National Agricultural Imagery Program) imagery were used to create geologic and fault maps on a USGS topographic base map, geologic cross sections and stereograms of collected field measurements (EROS, 2018). Fault scarp heights were collected as part of a guided undergraduate research project in which surveys were performed using a TopCon total station (Reed et al., 2019)

#### 4. Results

The results, which are largely based on the new map data (Plate 1; Appendix C), are presented in reverse chronological order for four different time intervals. Reverse chronology is used to illuminate the impact of the younger structures on older structures and unit deposition. The four time intervals are (1) Quaternary, (2) ~15 Ma to Pliocene, (3) Eocene to Miocene, and (4) Mesozoic time. (1) The youngest deformation within the study area is represented by the Quaternary fault scarps and related offsets along parts of the KSW fault zone. (2) Some fault strands of the ~NE-striking KSW fault zone and faults to both the NW and SE cut the Kane Wash Tuff providing a lower age bracket of middle Miocene, ~15 Ma; however, the upper age bracket is poorly constrained but is provided by the angular unconformity at the base of the Quaternary deposits. These Miocene-Pliocene faults lack scarps, cut the Oligocene to Miocene tuffs and older units, and are covered by the youngest Quaternary fluvial and alluvial sediments. (3) Before the inception of the KSW fault zone a period of erosion and deposition of both sedimentary rocks (the Ecs unit, Plate 1) and ash-flow tuffs occurred. (4) Those deposits unconformably overlie Paleozoic rocks which were shortened in the Jurassic-Cretaceous Sevier fold-thrust belt deformation. This shortening is represented by the DT and MVT and associated folds in the Delamar and Meadow Valley mountains, respectively (Plate 1; Figs. 1, 2).

Two domains of Miocene-Pliocene extensional faults are defined here, the NW domain and SE domain, which lie on opposite sides of the KSW fault (Plate 1; Figs. 1, 2, 12). The NW domain lies generally in the southern Delamar Mountains and the SE domain lies in the Meadow Valley Mountains. The major faults in the SE domain have strikes and displacements that are similar to – but not the same as – the major faults in the NW domain. The number of faults, their style of termination, offset stratigraphy, amount of total extension, and the general extension direction

are different between the two domains, as detailed below. The map data show fault terminations at the KSW fault with no indication that these faults are older faults that were offset by the KSW fault zone (Plate 1; Fig. 12). Some of the larger faults in both the NW and SE domains are buried by the youngest Quaternary alluvium or fluvial deposits or are exposed cutting only bedrock which gives no indication of a Quaternary slip history, but does not exclude Quaternary deformation. These faults cut the youngest ash-flow tuffs, the Ecs, and the Paleozoic rocks shortened in Sevier-related deformation with the youngest ash-flow tuffs down-dropped more than ~300 m (1000 ft) as measured from stratigraphic separation. The large offsets of these faults, which are consistent with their slip history, can be as old as latest Miocene, post KSW caldera eruption, and coeval with the KSW fault zone.

### ***KSW fault zone***

Displacement along the Cenozoic KSW fault zone is both down-to-the-NW normal dip-slip and left-lateral strike-slip along multiple strands that offset and capture the pre-existing tectonostratigraphy (Figs. 1, 2; Plate 1). Across the KSW fault zone normal vertical ranges from ~100 to 400 m at a minimum, as measured from exposures of tuffs in the Meadow Valley Mountains – the footwall of the KSW fault zone – to exposures of the same tuffs in the hanging-wall of the KSW fault and KSW-related faults. The left-lateral offset of the KSW fault is more difficult to quantify within the map area because no piercing points are directly observed, but the eastward extent of Cambrian exposures above the DT in the Delamar Mountains and the most northeastern exposures of Cambrian rock in the Meadow Valley Mountains are offset left-laterally ~13 km along strike of the KSW fault zone.

The KSW fault has a long-lived Quaternary and Miocene-Pliocene slip history because some strands offset Quaternary deposits and others are covered by them. Some strands that are

overlain by Quaternary deposits were active during or after the middle-to-late Miocene time (<15 Ma), because they cut ash-flow tuffs of that age, which are members of the Kane Wash Tuff.

Thus, the KSW fault may have been active for as much as ~15 m.y.

Quaternary deformation along the KSW fault zone is demonstrated by fault scarps that strike NE-SW along the KSW valley floor (Plate 1; Figs. 1, 2, 12; Reed et al., 2019). Most of the scarps face NW, show left-laterally offset washes and down-to-the-NW displacement of Quaternary surfaces. The exception is fault KSW2, which faces SE, indicating a down-to-the-SE component of offset along this strand of the KSW fault zone (Plate 1; Fig. 12). Quaternary fault scarps along the KSW fault zone measure from ~8-13 m in height (Reed et al., 2019) and exposures near the Meadow Valley Mountains place rocks as old as Cambrian next to Quaternary alluvium. Even though the apparent offset of the along-strike Cambrian exposures – exposed only as hanging-wall rock of the DT – is left-lateral, the presence of these scarps suggests that a nontrivial component of the total slip along the KSW fault is normal.

The KSW fault zone is ~5 km wide, separates the NW and SE domains, and controls the morphology of the KSW Valley, which drains southwestward and into the Coyote Springs Valley (Fig. 2). This drainage pattern is notable because the southwestern tip of the KSW fault zone, the southern Coyote Spring fault, and the northern Wildcat Wash fault spatially coincide with the intersection of KSW and Coyote Spring valleys (Fig. 2; Page and Pampeyan, 1996; Abdelhaleem, 2022).

The boundary between the NW domain and the KSW fault zone proper is the previously documented and named Willow Springs fault (Plate 1; Figs. 1, 2, 12; Tschanz and Pampeyan, 1970; Page et al., 1994). The Willow Springs fault is not well exposed within the study area but generally strikes ~035° and bends to ~045° northeast of the study area (Swadley et al., 1994).

Upon visual inspection the Willow Springs fault does not have Quaternary fault scarps, but this may be due to scarp erosion. Because other faults with NE-strikes are left lateral, the Willow Springs fault may have left-lateral offset and if so, it is part of the KSW fault zone. Where this fault can be accurately located it has a minimum vertical stratigraphic separation of ~200 m based on unit thicknesses and the juxtaposition of the Harmony Hills Tuff and Pennsylvanian Bird Spring Formation. Along the southwestern portion of the trace of the Willow Springs fault, it appears that the fault either steps over to another nearby structure or bends and splays southward, but the relations are obscured by Quaternary deposits.

The boundary fault between the SE domain and the KSW fault zone is fault MV1, the southeasternmost fault in the KSW fault zone. Fault MV1 strikes subparallel to the Willow Springs fault. In general, fault MV1 has an attitude of  $\sim 220^\circ/57^\circ$  NE – however, some subsidiary surfaces can dip as much as  $88^\circ$ . Strikes range from NE to ENE. Fault MV1 or faults that abut it cut older and middle Quaternary alluvium as evidenced by the along-strike Quaternary fault scarps and offset Quaternary units. At least two sets of slickenlines exposed within the damage zone of MV1 indicate both strike-slip and dip-slip displacement at different elevations along the fault surface. The dip-slip set measures  $\sim 53^\circ/278^\circ$ , while the strike-slip set, where measured along the northward bend of the lenses, has an attitude of  $\sim 02^\circ/005^\circ$  or nearly horizontal. The latter typically occurs higher in elevation along the slip wall. The presence of two distinct slip directions strongly suggests that slip along the KSW fault has varied through time. Along the northern trace of MV1, the fault abuts or splays with another strand of the KSW fault zone and places the youngest Miocene ash-flow tuffs in its hanging wall adjacent to Silurian and Devonian rocks in its footwall.

Near the center of the map area, fault MV1 captures a lens of tilted tectonostratigraphy including a previously existing low-angle normal fault within its hanging wall (Plate 1; Fig. 12). The low-angle fault juxtaposes Ordovician Ely Springs Dolomite and Devonian units such that it omits at minimum the Ordovician Eureka Quartzite and at maximum part of the earliest Ely Springs Dolomite as well (Plate 1; Figs. 2, 12). This low-angle normal fault is cut by high-angle faults genetically linked to the KSW fault zone. This pre-existing low-angle normal fault is offset a minimum of ~400 meters down-to-the-NW, when compared with the elevation of the same low-angle normal fault to the south in the Meadow Valley Mountains. The low-angle normal fault is documented in previous work (Scott et al., 1994). The exposed low-angle normal fault(s) is cut, and potentially reactivated, by the active and/or abandoned Miocene strands of the KSW fault zone. However, no ash-flow tuffs are exposed within the same fault block to provide a timing bracket. In addition, a higher low-angle normal fault in this lens places lower Devonian units atop the Ordovician Ely Springs Dolomite, omitting a portion up to the entirety of the Ely Springs Dolomite (Map Plate, Fault Map). Southwestward within the Meadow Valley Mountains, another low-angle normal fault places youngest Ordovician to Silurian and oldest Devonian rock atop rocks of the Ordovician Pogonip Group (Plate 1; Figs. 2, 12). This fault is used as a marker to determine offset along several faults within the SE domain (Plate 1). These low-angle normal faults, where exposed, have small stratigraphic omission and cannot be linked causally to a larger detachment event such as the Mormon Peak detachment to the east or the Seaman breakaway and Stampede detachment to the north.

### ***NW domain***

The structural style of the NW domain is marked by a network of NNE-SSW to NNW-SSE, ~E-W- and NE-SW-striking faults that are interconnected and apparently synchronous as indicated

by various abutting or branching relationships (Fig. 12, Plate 1 – Appendix A). In this network, faults with the smallest offset reach their topological termination against or into larger faults as is typical of a fault network (Plate 1; Fig. 12; Peacock et al., 2016). Extension within the NW domain is primarily directed ENE-WNW, or to  $\sim 307^\circ$ , with overall down-to-the-WNW displacement via the large high-angle faults that form the primary tectonic grain within the NW domain (Fig. 12). The large faults, such as GB and DM1, typically strike from  $\sim N10^\circ W$  to  $\sim N20^\circ E$ , sub-parallel to each other (Plate 1; Figs. 1, 2, 12). Measured from map data, vertical stratigraphic separation on the relatively large faults ranges from  $\sim 100$ – $300$  m. The small faults strike orthogonal to sub-orthogonal to and abut the large faults. These orthogonal faults are one of the defining features of the fault network of the NW domain and are virtually absent within the SE domain. Typically, these smaller faults within the NW domain fault network have down-to-the-SE or down-to-the-NW vertical stratigraphic separation of  $\sim 1$ – $3$  m though a few have vertical separation on the order of  $\sim 10$ – $15$  m. Some of the smaller faults in the NW domain fault network have intersections that are x-nodes which indicate that the faults with different strikes are coeval and that the faults operated as a network to transfer strain among the faults (cf., Peacock et al., 2016). The larger faults control this deformation and I will present data on the major faults of the NW domain from east to west below.

Fault GB is  $\sim 30$  km long and strikes N-S, subparallel to the range-bounding Coyote Spring fault to the west (Plate 1; Figs. 2, 12; Page, et al., 1990; Scott, et al., 1990; Page and Pampeyan, 1996; Anderson, 1999). To the north of the map area, fault GB appears to terminate against either a strand of the left-lateral Maynard Lake fault of the Pahranaagat shear zone or a NE-SW striking strand of the Coyote Spring fault (Fig. 2; Scott et al., 1990; Scott et al., 1995). Within the map area, the low dip of the Tertiary ash-flow tuffs on either side of fault GB and the relatively

straight map trace suggest that this fault is high angle. Minimum vertical stratigraphic separation along fault GB is measured from offset ash-flow tuffs (Plate 1) and is ~200 m. Fault GB places Cambrian Highland Peak Formation of the hanging wall of the DT and overlying tuffs (Harmony Hills Tuff, Hiko Tuff, and Delamar Lake Tuff) on the W down against Devonian and Pennsylvanian-Permian rock of the lower imbricates of the DT and overlying tuffs (Harmony Hills Tuff, Condor Canyon Formation, Leach Canyon Formation). The older rocks are in the hanging wall of the normal fault indicating that within the study area fault GB cuts or reactivates the DT. Normal slip along fault GB was less than the thrust displacement along the DT because the older-over-younger relationship of the Cambrian hanging-wall rock and younger footwall rock is maintained. The southernmost trace of fault GB is buried under alluvium, where its trace apparently abuts the KSW fault zone. Cross-cutting relationships constrain the age of fault GB to be younger than the middle Miocene tuffs and older than the Quaternary alluvium at the surface. Fault DM1 is a down-to-the-NE fault that places the Cambrian Highland Peak Formation in its hanging wall against ash-flow tuffs and Cambrian rock of the same formation in its footwall block with a vertical stratigraphic separation that cannot be readily determined from available map data but is likely less than 100 m (Plate 1, Fig. 12). To the S, the trace of fault DM1 abuts fault GB where it either truncates against or transfers slip onto fault GB. To the NW, fault DM1 appears to die out; along its tip, there are small step-overs and truncations (Plate 1, Fig. 12). Several of the NE-SW striking small faults of the network abut or transfer their slip onto fault DM1 and abut another fault of the primary fault set, DM2. Fault DM2 strikes N-S and has down-to-the-W displacement with a minimum vertical stratigraphic separation of ~100 m estimated from the difference in average elevation of a Tertiary ash-flow tuff, the Condor Canyon Formation, in its hanging-wall and footwall blocks

(Plate 1; Figs. 2, 12). The offset of fault DM2 could be significantly higher due to differences in elevations of tuff deposition related to paleorelief and the lack of an overlying tuff unit in both the hanging-wall and footwall blocks directly adjacent to fault DM2. A series of NNE-SSW striking normal faults either splay off or transfer slip onto fault DM2; two of the major splays, DM3 and DM4, branch from fault DM2 (Plate 1; Fig. 12). DM3 has down-to-the-NW displacement and DM4 has down-to-the-southeast. The map patterns and dip directions of both DM3 and DM4 suggest that they are coeval and operate simultaneously with fault DM2. All three faults, DM2, DM3, and DM4, are buried by the youngest Quaternary fluvial deposits and alluvium where not exposed in bedrock.

### ***SE Domain***

The SE domain is exposed in the Meadow Valley Mountains and is more extended in the WNW-ESE direction, directed  $\sim 289^\circ$ , than the NW domain (Fig. 12). The SE domain is characterized by NNE-SSW-striking high-angle normal faults that abut and either transfer slip from or terminate into fault MV1 and its along-strike correlatives. These strands have down-to-the-WNW or down-to-the-W displacement. Many of the extension-related faults in the northern Meadow Valley Mountains are exposed in only bedrock, limiting our ability to constrain their youngest age. This means that it is impossible to exclude Quaternary slip even though scarps are not exposed, but these faults do not cut the youngest Quaternary sediments. All faults within the SE domain terminate where they abut fault MV1 on their northern end. Overall, the prominent extension-related faults in the SE domain have a westward bend in their strike to become sub-parallel to the KSW fault zone as one follows their strike to the S (Plate 1; Fig. 12). I will discuss the major SE domain faults from E to W.

Faults MV2a, b, and c (map plate) strike N-S and have down-to-the-W displacements. Notably MV2 faults strike similarly to faults exposed within an active lens of the KSW fault zone along most of their strike, but when their map trace is followed north along strike these faults bend northwards to terminate against fault MV1. Southward, along strike, fault MV2 transverses the Meadow Valley Mountains to eventually abut to a southward bending branch of the KSW fault zone or the Wildcat Wash fault. The dips of the Tertiary ash-flow tuffs are different on either side of the main branch of fault MV2 such that the youngest Tertiary ash-flow tuffs in the hanging-wall dip WNW, while the older ash-flow tuffs located within the footwall dip to the E. Faults MV3a, MV3b, and MV3c strike parallel to fault MV2, and also have down-to-the-NNW displacement, as determined from offset Cambrian stratigraphy. Upon visual inspection of satellite imagery, faults MV3a, b and c continue southward from the study area in the Meadow Valley Mountains where they appear on satellite imagery to transverse through Wildcat Wash and interact with the Wildcat Wash fault (Figs. 2, 12). The total slip of these faults changes along strike, but the primary strand of this fault has portions where vertical stratigraphic separation is a minimum of ~200 m based on the vertical positions of rocks in the Cambrian Highland Peak Formation, the Ordovician Pogonip Group, and the previously existing tectonostratigraphy that was generated by the low-angle normal faults. Faults MV3a, b, and c also strike N-S and abut the KSW fault zone at fault MV1 similar to the MV2 faults. Southward along strike, these faults bend to strike NE-SW with down-to-the-northwest displacement. The southern ends of the MV3 faults are buried under alluvium, but project southwestward to intersect with either the southern part of the KSW fault zone (where the KSW fault zone bends southward and splays) or with the Wildcat Wash fault (Pampeyan, 1993).

Faults MV4a and b strike ENE-WSW and abut or splay from the KSW fault zone. Fault MV4a has down-to-the-NNW displacement, while the antithetic splay, fault MV4b, has apparent down-to-the-SSE displacement. Both faults MV4a and MV4b cut the low-angle normal fault in the KSW fault lens and place the hanging-wall late Ordovician-Silurian stratigraphy against the Ordovician rock of the footwall of that same low-angle normal fault. Offset along fault MV4a cannot be determined definitively because of a lack of clear stratigraphic markers but can be assumed to be hundreds of meters at the northern tip and as low as 10s of meters after the splay into the antithetic strands based on stratigraphic separation. The western antithetic splay MV4b also cuts the same tectonostratigraphy, both of which bound a block that only exposes the upper plate of the low-angle normal fault. Faults MV4a and MV4b interact with a part of the KSW fault zone to the south or are buried by Quaternary sediments where they either remain parallel to or abut the KSW fault zone along fault MV1. From cross-cutting and abutting relationships the age brackets on these faults can be assumed to be the age of the Miocene tuffs or younger and older than late Quaternary as they do not cut the latest Quaternary sediments or the KSW fault zone itself.

### ***Timing of the Eocene Conglomeratic Sediments in Relation to Structures***

Map relations of the Ecs in the Delamar and Meadow Valley mountains show that it was deposited after Sevier-related deformation and before KSW-fault-zone-related deformation. Where exposed in the Delamar Mountains, the Ecs unit overlies the lowest imbricate of the MVT. Within the Meadow Valley Mountains, the Ecs unit overlies both Devonian rocks of the MVT hanging wall and MVT footwall rocks of the upper Mississippian Chainman Shale and Scotty Wash Quartzite, and lower Pennsylvanian-Permian unit. The Ecs thickens and thins with changes in paleorelief in both the Delamar and Meadow Valley mountains.

Preliminary detrital zircon analysis was performed on Ecs samples to better determine the age and provenance (Appendix B). Samples were taken at several locations from sandstones within the conglomeratic portion of the Ecs unit in the Delamar Mountains where the unit overlies an imbricate thrust and underlies the tuffs (Plate 1). These preliminary analyses reveal that the maximum age of deposition is  $39.0 \pm 0.3$  Ma (Plate 1; Appendix B; T.S. Bidgoli, 2020, personal commun.; Moore et al., 2020). Consistent with the Ecs overlying this Sevier-belt thrust, detrital zircon grains from the new analyses match DZ age distributions from units in Sevier thrust plates (Fig. 11). These units are chiefly Precambrian to Cambrian quartzites – the Wood Canyon Formation, the Zabriskie/Prospect Mountain Quartzite, the Stirling Quartzite, or the Johnny Formation – and the Ordovician Eureka Quartzite which are not exposed in the nearby upper plate of the DT. An additional subset of Mesozoic zircon grains was likely sourced from a granitic stock in the Grant Range. Bidgoli (pers. comm. 2020) notes that grains from late Paleozoic quartzites like the Devonian Oxyoke Canyon Sandstone and the Mississippian Scotty Wash Quartzite, commonly sourced from upper plates of local thrusts, are lacking in the Ecs but occur in Cretaceous-Eocene sediments northwards such as the Newark Canyon, Elko, and Sheep Pass formations (Druschke et al., 2011; Canada et al., 2019). There are no exposures as deep as the Cambrian quartzites like the Prospect Mountain Quartzite within the Delamar or Meadow Valley mountains that could supply the basin in which the Ecs is deposited, and the Ecs unit overlies the Mississippian quartzite and shales. Consequently, the grains are likely sourced from the former hinterland plateau to the northwest because the appropriate Cambrian and Precambrian quartzites are exposed in the upper plate of the Gass Peak thrust.

The Ecs underlies the Tertiary ash-flow tuff section, and faults of both the NW and SE domains as well as the KSW fault zone cut the Ecs. These relations make it relatively older than those units and structures, consistent with the 39 Ma detrital zircon age.

### ***Sevier Thrusts – Delamar and Meadow Valley Thrusts***

The Delamar and Meadow Valley thrusts are exposed in the Delamar and Meadow Valley mountains, respectively (Plate 1; Figs. 1, 2, 12). The DT generally strikes  $195^{\circ}$ , whereas the MVT strikes  $\sim 180^{\circ}$ ; both dip W. The DT juxtaposes middle-late Cambrian Highland Peak Formation strata against Devonian units along the main thrust (main imbricate), Devonian atop Mississippian along a lower (the upper middle) imbricate, Mississippian atop Pennsylvanian (the lower middle imbricate), and Pennsylvanian atop Pennsylvanian rock along the lowest imbricate. The MVT places Silurian and middle-to-late Devonian strata against late Mississippian and early Pennsylvanian rocks in its footwall. Portions of both the hanging wall and footwall strata of the MVT are overlain by the Ecs unit. The DT, DT imbricates and MVT are all overlain locally by the Tertiary ash-flow tuffs (Plate 1; Figs. 2, 12; Longwell et al., 1965; Tschanz and Pampeyan, 1970).

Fault GB dips west and places older Paleozoic rocks of the DT thrust plate over younger Paleozoic rocks of the footwall and is demonstrably a normal fault where it cuts ash-flow tuffs to the north, juxtaposing younger tuffs in the hanging wall and older tuffs in the footwall. These map relationships indicate that fault GB must either cut out the DT or reactivate it. Most of the Paleozoic hanging-wall rocks of the DT dip gently. Whereas, to the east of fault GB, the Paleozoic DT footwall rocks dip relatively steeply and lie in thin thrust imbricates that overlie shallowly dipping Pennsylvanian-Permian rock (Fig. 12). The ash-flow tuffs that overlie both the DT plate as well as the footwall imbricate plates also dip gently, but the ash-flow tuffs that

overlie the Paleozoic rocks in the hanging-wall block of fault GB dip more steeply than those in the footwall of fault GB. This geometry indicates a small amount of differential tilting across fault GB after tuff emplacement.

NNE-SSW trending, gently plunging folds are exposed within the southern Delamar Mountains (Plate 1). These folds include a previously documented range-scale anticline in the DT thrust plate that trends sub-parallel to the strike of the lower imbricates of the DT (Plate 1; Fig. 12; Scott et al., 1995). Within the eastern limb of this range-scale fold, I documented a smaller parallel syncline-anticline pair that are restricted to the upper plate of the DT (Plate 1). The fold pair trends subparallel to the large range-scale hanging-wall anticline. The range-scale anticline is dissected by the NW domain fault network (Page et al., 1990). The western limb of the range-scale anticline continues to young westward until the strata are truncated across-strike by the Coyote Spring fault (Plate 1; Figs. 2, 12).

In the Meadow Valley Mountains, late Cambrian Nopah Formation strata that are the same as the DT upper-plate strata in the Delamar Mountains are exposed in a fault-bounded block. The DT itself is not exposed in the Meadow Valley Mountains because NW-dipping fault MV4 drops it down-to-the-NW. The Ordovician Pogonip Group exposed in the Meadow Valley Mountains is here considered a stratigraphically higher part of the DT plate.

Both the MVT and DT continue beyond the map area along strike. From where the DT is cut by the KSW fault on the S, the thrust continues northward in the Delamar Mountains for about 70 km (~43.5 mi) and is correlated to additional thrusts discussed below (Fig. 1; Pampeyan, 1993; Felger and Beard, 2010). The northern end of the MVT is cut by the KSW fault zone, but to the south, out of the study area, the MVT appears to die out along or into the Bunker Hills folds (Fig. 2; Pampeyan, 1993; Beard et al., 2009; Felger and Beard, 2010). Upon visual inspection of aerial

and satellite imagery along strike of the MVT, the same hanging-wall-footwall stratigraphic relationship appears to continue south on the SE side of the Meadow Valley Mountains for more than 25 km.

## 5. Discussion

### *KSW fault zone*

The main component of offset along the KSW fault zone, strike-slip, varies in magnitude along strike. The apparent left-lateral offset of the DT in the Delamar Mountains and upper plate exposures of the DT in the Meadow Valley mountains is ~14 km. This amount is ~2-5 km greater than that of the apparent left-lateral displacement of the KSW caldera wall (cf., Harding et al., 1991). This relation suggests greatest offset occurs nearer to the thrust fault exposures and along the central or west-central portion of the KSW fault zone.

Relative to the primary tectonic grain of the BRP (~N-S), the NE-strike and large strike slip of the KSW fault and structural differences across it are consistent with it being a transfer fault zone. Transfer fault zones are essential components of rift systems at which primary rift structures terminate forming abutting geometries. Transfer fault zones also accomplish the compartmentalization of rifts into subprovinces via strike-slip and oblique-slip faults that strike at a high angle to the rift trend (Plate 1; Figs. 1, 2). This case study suggests that the KSW fault transfers strain between faults in the SE and NW domains accommodating differences in fault geometries, extension direction and distribution of extension. In the SE domain extension is WNW-ESE, ~289°, directed along a few steeply dipping normal faults (Plate 1; Figs. 12, 13). In contrast, NW domain extension is more NW-SE, ~307°, directed along a fault network conducting overall more NE-SW directed extension than the E-W extension of the SE domain. Differences in distribution of extension across the KSW fault zone are evidenced by a concentration of faults in the NW domain along the southwestern KSW fault when compared with the SE domain, with fewer faults that are more evenly distributed and generally parallel (Plate 1; Fig. 12). A disparity in amounts of extension across the KSW fault is due to the

differences in extension in the NW and SE domains. These differences are exemplified by the distance between the DT and MVT, however this disparity cannot be measured with confidence because the DT exists at depth (Plate 1).

The Miocene-Pliocene directions of extension north and south of the KSW fault zone are different when compared to previously suggested directions of Quaternary extension within BRP. Geodetic data show that contemporary extension is predominantly E-W within the BRP (Hammond and Thatcher, 2004; Kreemer et al., 2010). To the SW of the KSW fault zone the Wildcat Wash fault, and to the NW, the Coyote Spring fault both accommodate E-W directed Quaternary extension (Fig. 2; Page et al., 1990; Page and Pampeyan, 1996). In comparison, the Miocene-Pliocene extension in the SE domain is WNW-ESE,  $\sim 289^\circ$ , and the Miocene-Pliocene NW domain extension is more NW-SE,  $\sim 307^\circ$ . These new map data demonstrate that extension direction has changed through time.

The new map data also show that extension, including strike-slip and normal faulting, began in middle Miocene time or later; in particular many faults cut the  $\sim 15$  Ma Kane Wash ash-flow tuff and are overlain by Quaternary alluvium. This timing is consistent with other faults in the NBR-CBR boundary zone. The left-lateral Maynard Lake fault to the north is shown to have both Quaternary and Miocene or later offset (Fig. 2; Muhammad, 2016). The eastern boundary fault for the NW domain – fault GB – abuts to the north against the Maynard Lake fault indicating that the NW domain has deformation that can be as old as Miocene. In addition, no extensional faults that cut only Paleozoic rocks or Paleozoic rocks and only part of the tuff section were identified. This lack suggests that extension did not begin until after the deposition of the youngest tuff cut, the  $\sim 15$  Ma Kane Wash Tuff. This timing of onset of extension is similar to that in the CBR and

consistent with a major extensional period in the NBR (e.g., Taylor et al., 1989; Bidgoli et al., 2015).

### ***Kane Springs Wash Fault Zone and the NBR-CBR boundary Zone***

When considered within the context of the larger BRP rift, the boundary between the NBR and CBR is interpreted to be an E-W to NE-SW oriented long-lived zone of transfer faults defined by the KSW fault zone, Pahranaagat shear zone, structures within the Timpahute lineament, and the Caliente-Enterprise zone (Figs. 1, 2, 3, 4; Taylor et al., 2022). These fault zones all strike at a relatively high angle to the Basin and Range rift boundaries (Figs. 1, 2, 3) and have been interpreted as transfer zones (Fig. 2; Tschanz and Pampeyan, 1970; Faulds and Varga, 1998; Rowley, 1998; Bidgoli, 2005; Price, 2017; Evans, 2018; Peck, 2018; Gomes et al., 2018; Ely and Taylor 2018; Reed, 2019; Abdelhaleem et al., 2020; Reid et al., 2020; Taylor et al., 2022). Here, these structures are interpreted, all together, to form a major, broad tectonic and geomorphic boundary zone in the Miocene to Quaternary that separates the NBR subprovince from the CBR subprovince. This boundary zone is evident in structures active as old as Miocene, modern seismicity in the southern Nevada seismic belt, modern topography, gravity data, and the terminations of ~N-S striking normal faults against the E-W to NE-SW left-lateral faults (Figs. 1, 2, 3, 4; Ekren et al., 1976; Jayko, 1990, 2007; Dohrenwend, et al., 1996; dePolo, 1998; Kucks, 1999; Kucks et al., 2006; Kreemer et al., 2010; dePolo and dePolo, 2012). The boundary zone, thus, has the characteristics of and appears to be a rift segment boundary. Notably, the width of the NBR-CBR boundary changes along the trend of this zone, which is consistent with slip transfer among faults (Figs. 1, 3, 4). From these data, I interpret the KSW fault zone as the southernmost fault within the NBR-CBR boundary zone in its widest part.

During the Miocene-Quaternary, the NBR-CBR boundary zone has likely performed as a transfer zone and rift segment boundary in which different structures may have been active through time. Within the NBR-CBR boundary zone, the most recent faulting youngs southward, suggesting that deformation is focused southward towards the KSW fault zone through time. All of the structures were active in Miocene-Pliocene time, but the northern-most structures were abandoned by Quaternary time. Faults of the Timpahute lineament, at the northernmost edge of the NBR-CBR boundary zone, do not have any indication of Quaternary displacement along these E-W-striking structures. Much of the motion on faults of the Timpahute lineament post-dates the ~18.5 Ma Hiko Tuff and the faults are overlain by Quaternary deposits – that is, most deformation occurred during Miocene or Pliocene time (Tschanz and Pampeyan, 1970; Taylor et al., 2000; Bidgoli, 2005, Abdelhaleem et al., 2020; Reid et al., 2020). However, some evidence, such as the southern limit of the Oligocene Seaman breakaway-Stampede detachment system, suggests that the Timpahute lineament may have been active during Oligocene time (Fig. 2; Taylor and Bartley, 1992; Axen et al., 1993). Map data within the PSZ provides evidence of post ~15 Ma Miocene-Pliocene offset along all faults and Quaternary offset along its boundary faults on the northwest and southeast but does not have Quaternary fault scarps within its interior (Muhammad, 2016; Price, 2017; Evans, 2018; Peck, 2018; Ely and Taylor, 2018). The KSW fault zone has evidence of both post~15 Ma Miocene-Pliocene and active Quaternary deformation (Plate 1; Figs. 5, 6, 13; Pampeyan, 1993; Swadley et al., 1994; Anderson, 1999; Abdelhaleem et al., 2020; Reid et al., 2020). These age relations suggest that the NBR-CBR boundary zone has either migrated slightly southward through time or the zone initiated as a wide zone and the Miocene and Quaternary fault activity has been focused in the southern portion with time.

### ***Kane Springs Wash Fault and the Mormon Peak Detachment***

The Mormon Peak detachment is a Miocene regional low-angle normal fault exposed ~25 km to the SE of the KSW fault zone in the CBR (Fig. 2; Wernicke et al., 1985; Wernicke et al, 1990; Axen, et al., 1990; Swanson and Wernicke, 2017). The Mormon Peak detachment was active at ~14-13 Ma based on structural relationships and low-temperature apatite and detrital zircon thermochronology (Bidgoli et al., 2015; Swanson and Wernicke, 2017). The ~15 Ma KSW caldera is post-dated by both the KSW fault zone and the Mormon Peak detachment, thus, the age brackets allow the possibility that they operated synchronously. The E-W to NE-SW (~275°) extension direction of the Mormon Peak detachment is similar to the slip direction of the KSW fault zone proper and the direction of extension across it. (Figs. 2, 5; Wernicke et al., 1985; Wernicke et al., 1990; Axen et al., 1990). To assess whether it is possible that the Mormon Peak detachment underlies the study area in the Meadow Valley Mountains, estimates of the depth of the Mormon Peak detachment zone were made. The estimates are based on projecting it from the nearest exposures using a dip of ~20°-25° to the NW which suggests that the detachment exists at a depth of ~ 9 km beneath the Meadow Valley Mountains (cf., Stockli et al., 2002; Bidgoli et al., 2015; Swanson and Wernicke, 2017). The average depth to the brittle-ductile transition zone in the BRP is ~10-15 km, a slightly greater depth. Based on the similarity in age, onset, overall extension direction, and spatial proximity, a genetic relationship between the KSW fault zone and the Mormon Peak detachment is possible. However, map relationships in this study cannot resolve that relationship. The data presented in this study allow the possibilities that the KSW fault (1) operates only within the upper plate of the Mormon Peak detachment, (2) that the KSW fault zone acted as a lateral termination of the Mormon Peak detachment and slip was transferred between them, (3) the KSW fault cuts the Mormon Peak detachment in the brittle realm, or (4)

the KSW fault zone is genetically linked in Miocene time to the Mormon Peak detachment, but has continued slip into the Quaternary independent of the detachment because no evidence has been presented that the Mormon Peak detachment has a Quaternary slip history. For reasons of timing of onset, spatial proximity, overall extension direction across both faults, and the interpretation that the KSW fault zone is a transfer fault that is part of the NBR-CBR boundary zone, the favored options are that the KSWF either cuts the Mormon Peak detachment or is the lateral boundary for it during the Miocene.

### ***3-Dimensional Deformation***

The KSW fault zone separates the generally 2-dimensional deformation of the SE domain from the fault network of the NW domain, which is suggested to accommodate 3-dimensional deformation. In Andersonian fault theory, conjugate normal faults develop with strikes perpendicular to the direction of the principal extension – this assumes no strike slip component along the faults. Such conjugate faults occur in plane strain, 2-dimensional deformation (Collanega et al., 2020). However, many models and examples of extensional fault networks are orthorhombic in map view and have faults that are not perpendicular to the primary extension direction (Krantz, 1989; Miller et al., 2007). These faults can develop stepwise through time or the faulting may be synchronous (Reches, 1983; Henza et al., 2010; Collanega et al., 2020). Fault networks, particularly orthorhombic normal faults, are oriented such that they accommodate overall extension in localities with complex strain fields and are documented in rift segment intersections such as in the Dead Sea basin or the East African rift system (Reches, 1983; Henza et al., 2010; Collanega et al., 2020). The suggestion of 3-dimensional deformation in the NW domain is based on (1) the non-parallel boundaries of the network and (2) the geometries, abutting fault terminations, and timing of faults within the network of synchronous N-S long

faults with two sets of cross faults (Plate 1; Figs. 2, 12; Reches, 1983; Wilkins and Schultz, 2003; Henza et al., 2010; Peacock, 2016; Collanega et al., 2020). The NW domain extensional network is contained within the hanging wall of the NNE-striking fault GB and the footwall of the N-striking Coyote Spring fault, forming a trapezoid-shaped block between them. A change in shape of the volume of rocks in the NW domain is required as faults move blocks with non-uniform shapes within the trapezoid. Thus, the deformation is likely 3-dimensional and achieves overall E-W extension between the non-parallel boundary faults, fault GB and the Coyote Spring fault. The NW domain fault x-nodes geometries have differing amounts of offset but do not offset each other, and thus, also suggest that deformation within the NW domain is 3-dimensional (Plate 1; Figs. 2, 12; Reches, 1983; Wilkins and Schultz, 2003; Henza et al., 2010; Peacock, 2016; Collanega et al., 2020).

### ***Ecs and Eocene Drainages***

The relatively immature texture of the clasts and the DZ grain analyses provided by T.S. Bidgoli and K. Moore (personnel communication) suggest that the sediment source for the Ecs unit is not solely the hanging-wall rocks of the DT because it includes zircons from Precambrian and Cambrian quartzite units not exposed in the DT plate. Given (1) our current understanding of the paleogeomorphology of the Sevier fold-thrust belt with a highland to the W and N of KSW (Taylor et al., 2000; Henry et al., 2008; Busby and Putrika, 2009; Long, 2012; Smith et al., 2014; Erdman et al., 2016; Smith et al., 2017; Cassel et al., 2018) and (2) that Precambrian and Cambrian quartzites are exposed in the Gass Peak thrust sheet just to the west (Plate 1; Figs. 2, 6, 11, 12), I suggest that the source for the Ecs unit lies to the current N and W of the Delamar Mountains in the Sevier hinterland highlands, which include the Gass Peak plate (Plate 1; Figs. 1, 2). In addition, the detrital zircon analyses (Appendix B) require that ~39 Ma source rocks or

pyroclastic air fall provide sediment to the basin. Rocks of that age in the region lie to the north and are primarily pyroclastic units of the ignimbrite flare-up (Best et al., 2013a, b). Thus, the ~39 Ma grains could have been delivered via ~N-S streams or could be from air fall. The Ecs streams and lakes, may have collected air fall, and occurred near the DT. The position of the DT relative to this highland strongly implies that DT was not a hinterland thrust and that the DT lies in an intermediate structural position, structurally lower than the hinterland thrusts and higher than the frontal thrust. Using these data, I interpret that Ecs represents the erosional denudation of the former Sevier hinterland during Eocene time and that it was deposited along a slope between the hinterland highland and the frontal thrusts.

Although the Eocene topographic maximum existed to the N and W of the Ecs unit (Figs. 1, 2, 5), the stratigraphic and structural relationships show that the Ecs unit was deposited in a setting with pre-existing paleorelief (Plate 1; Figs., 1, 13, 14, ;Busby and Putrika, 2009; Long, 2012; Best et al., 2013; Smith et al., 2014; Cassel et al., 2014; Erdman et al., 2016; Smith et al. 2017). The DT is not presently directly overlain by the Ecs unit in the Delamar Mountains, however, given that the lower imbrications of the DT are covered by the Ecs unit in the Delamar Mountains, it is likely that the DT plate made a local high at the base of which was the depositional basin for the Ecs unit (Fig. 13). Within the Meadow Valley Mountains, the new map data show that the Ecs unit unconformably overlies both hanging-wall and footwall rocks of the MVT. The conglomerate facies of the Ecs is thickest in the Delamar Mountains, while the limestone facies is thickest in the Meadow Valley Mountains. This change from proximal clastic sediments to freshwater carbonates is an indication that the Ecs drained S and E, and that the environment shifted to a low energy setting during the latter stages of deposition. In summary, the changes in relative thickness of the two different facies of the Ecs unit suggest that the thick

conglomerate package was proximally located to the highland earlier in Ecs deposition and that a topographic sink existed farther to the SE or E of the KSW area, such as the basin in which the Claron Formation was deposited (Taylor, 1993; Goldstrand, 1994). This drainage direction is consistent with the position of the Sevier hinterland to the N and W.

Because of the limited thickness and distribution of the Ecs, it is unlikely that the Ecs strata were deposited in a primary Eocene drainage but existed as a part of a potentially interconnected fluvial system that would be common to a slope from a hinterland highland to a basin nearer to or in the foreland. While the new data cannot show that the Ecs was part of a series of connected or isolated drainages, deposits that are of similar age, composition, and spatial position relative to the Sevier hinterland are exposed in the region. Such rocks exist nearby within the Pahrangat shear zone, Mount Irish, the Timpahute Range, the Wah Wah Mountains, the North Pahroc Range, and other mountain ranges (Tschanz and Pampeyan 1970; Taylor et al., 2000; Jayko, 2007; Davis et al., 2010; Muhammad, 2016; Price, 2017; Smith et al., 2017; Evans, 2018). These deposits could represent other portion(s) of the same drainage system. Several sedimentary rocks that represent eastward drainages off the Sevier hinterland farther north in the northern NBR are well documented (Smith et al., 2017). These drainages terminate in lakes – such as Lake Uinta, Claron, and Gosiute – that were proximally located to Sevier frontal thrusts and primarily deposited atop the footwalls of these thrusts (Smith et al., 2017). The Claron Formation, which is exposed to the E and N of KSW primarily in southern Utah, overlaps in age with the Ecs unit and sits above the conglomeratic Grand Castle Formation or Triassic to Cretaceous units (Bowers, 1972; Taylor, 1993; Goldstrand, 1994; Eaton et al., 2018; Sanjuan et al., 2020). These units could represent the generation of accommodation space, in the east, in response to the topographic relief generated by Sevier-related deformation and to southwestward migrating dynamic

subsidence from slab rollback. The new data presented here, when taken in conjunction with the Eocene drainages suggest that a series of lakes and basins existed to the E of the Sevier hinterland highland and that the Sevier hinterland plateau was in part destroyed through erosion during Eocene time. Local reduction of the highland in the Miocene and later was increased by extension.

### ***Sevier Thrusts***

The stratigraphy, lithology and bedding attitudes across the DT in the Delamar Mountains are similar to that in separate Miocene fault blocks within the western Meadow Valley Mountains. These relations suggest that the DT occurs at shallow depth within the western Meadow Valley Mountains and is offset or reactivated by Miocene or later faulting. The gentle dip, stratal characteristics and facies of Cambrian strata exposed in both the Meadow Valley and Delamar mountains are similar and characteristic of the upper plate of the DT. Across faults MV1 and MV3, these strata are juxtaposed with Miocene ash-flow tuffs to the N and E, and Ordovician and Devonian rocks to the S and W (Plate 1; Figs.12, 14). These relations suggest that the DT occurs at shallow depth below the Ordovician and Cambrian units and was dropped down to the W by the Miocene faults MV1 and MV3. Fault MV3 locally places older over younger rocks because it cuts this thrust and has less offset than the thrust. Fault MV3 cannot be a reverse fault, because along strike it cuts and normally offsets both Miocene ash-flow tuff and Eocene paleorelief, and has the synthetic splay MV2 that cuts Miocene units. These relations also suggest that the Ordovician rocks in the hanging-wall block of fault MV4 – that exposes the low-angle normal fault – are part of the upper plate of the DT (Plate 1; Fig. 12).

The new map data lead to the suggestion that the DT and MVT are not the same thrust repeated by normal faults but part of the same imbricate stack with the DT being the highest and the MVT

being a lower imbricate. This interpretation is based on the bedding geometries, stratigraphic separation, and the close fault spacing of the DT and MVT within the KSW area. The stratigraphic separation of the DT is much greater than the stratigraphic separation of the MVT. The DT places Cambrian hanging-wall rock on top of Devonian footwall rock, while the MVT places Devonian rock in its hanging wall over Pennsylvanian rock (Map Plate). Miocene-Pliocene high-angle fault GB juxtaposes the uppermost and shallowly dipping plate of the DT adjacent to the lower imbricates, offsetting or reactivating the thrusts. The spatial and offset relations of the thrusts are characteristic of imbricate thrusts that functioned together and performed different roles in accommodating the along-strike changes in the Sevier belt at this latitude.

The Dry Lake thrust – exposed ~65 km to the south of the KSW – has a similar structural style, geometry, structural position within the Sevier belt, stratigraphic separation, and geometry as the DT and MVT imbricate system. The Dry Lake thrust sits in an intermediate structural position between the Sevier hinterland thrusts such as the Gass Peak thrust and the Sevier frontal thrusts like the Mormon and Muddy Mountain thrusts (Fig. 2). The Dry Lake thrust places Cambrian rock atop Devonian rock and has a structurally lower imbricate placing Devonian rock atop Pennsylvanian-Permian rock. The same pattern as our interpretations for the DT and the structurally lower MVT. Following the trace of the Dry Lake thrust along-strike northwards leads to the Bunker Hills folds which lie in the footwall of both the Dry Lake thrust and MVT or the MVT dies out southward into the Bunker Hills fold (Fig. 2). Thus, the Dry Lake and Delamar thrusts appear to be correlative.

Regional correlation of the Delamar and Dry Lake thrusts southwestward across the right-lateral Las Vegas Valley shear zone to thrusts that lay between the Wheeler Pass thrust, a Gass Peak

correlative, on the W and the frontal thrusts on the E are debatable (Figs. 1, 2). Both the Dry Lake and Valley thrusts previously were correlated to the SW to the Lee Canyon thrust and the Deer Creek thrust (Wernicke et al., 1988; Lundstrom et al., 1998; Page et al., 2005a, b). Both the Lee Canyon and Deer Creek thrusts contain lower Paleozoic rocks (Cambrian and Ordovician) in their hanging walls and upper Paleozoic and Mesozoic rocks in their footwalls (Fig. 2). The Lee Canyon thrust was previously suggested to be correlative to the Valley thrust across the Las Vegas Valley Shear zone, but the stratigraphic separation across the Lee Canyon thrust is more consistent with the Dry Lake thrust and DT (Fig. 2; Page et al., 2005a). The Lee Canyon thrust places Cambrian and Ordovician rocks atop Pennsylvanian-Permian rock, like the Dry Lake thrust and the DT but dissimilar to the Valley thrust which places Mississippian rocks atop Pennsylvanian-Permian rocks (Page et al., 2005b). The Deer Creek thrust also places Cambrian rocks atop Pennsylvanian rocks, similar to the Dry Lake and Lee Canyon thrusts. When taking into account the structural position, the relative stratigraphic separation, and the location of the Lee Canyon or the Deer Creek thrust when compared to the Valley thrust across the Las Vegas Valley shear zone it is difficult to support the conclusion that either the Lee Canyon or Deer Creek thrusts are laterally equivalent to the Valley thrust. It is far more likely that the Lee Canyon thrust is laterally equivalent to the Dry Lake thrust, and according to the interpretations proposed here, the DT.

The Wah Wah thrust, exposed ~160 km to the NE of KSW, is interpreted by this work, and others, to be the northward lateral equivalent of the DT (Taylor et al., 2000; Long, 2012). I concur and further interpret the DT correlative, the Dry Lake thrust, to be the southward lateral equivalent of Wah Wah thrust (Friedrich and Bartley, 2003; DeCelles, 2004; Yonkee and Weil, 2015). While the DT and MVT thrusts are not often considered in reconstructions of the Sevier

belt at this latitude, where typically only hinterland and frontal thrusts are considered, they play an important role in the final configuration in the Sevier belt.

### ***Overprinted Deformation***

Although it is common in overprinted terranes that younger deformation either obfuscates or exposes the older deformation, in the KSW area overprinting has done both. Overprinted deformation allowed for the exposure of older rocks used to complete the thrust correlation. The recognition of the DT in the Meadow Valley Mountains and this thrust correlation allowed for a more in-depth analysis of the slip of the KSW fault zone. Locally, older deformation related to the DT is such that it may have controlled some of the orientation expressed in Cenozoic extension from Miocene time such as fault GB but is unlikely to have controlled the youngest extension (Fig. 13). Although the DT is not well exposed at the surface its lower imbricates including the MVT are well exposed, both due to younger KSW-fault-zone-related deformation. The Miocene and younger faults offset and slightly obscure the former rugged highland constructed during Sevier-related deformation which built the basins for the deposition the Ecs rocks and subsequent ignimbrite-flareup-related tuffs. In general, Cenozoic extension created and/or exposed the many structures and stratigraphy vital to increasing our understanding in the KSW area and the BRP as a whole.

## 6. Conclusions

The KSW area exposes overprinted deformation in which Miocene-Quaternary faulting, including the Kane Springs Wash transfer fault zone and an associated rift segment boundary, overprinted a portion of the earlier Jurassic-Eocene Sevier fold-thrust belt. This part of the Sevier belt lies between the frontal thrusts and the hinterland highland. It includes the DT which is correlated to regional thrusts to the north and south.

### *The KSW Fault Zone*

The KSW fault zone operates as a transfer zone with differing magnitudes, directions, and styles of extension in the NW and SE domains, which lie on opposite sides of it. The NW domain comprises a dense fault network with fault geometries and intersection relations that can only be accomplished through 3-dimensional deformation and slip transfer between the KSW fault zone and the fault network. In contrast, the SE domain includes faults that are relatively evenly spaced and transmit slip to or from the Wildcat Wash fault and the KSW fault zone. Slip from both the NW and SE domains is transferred to the KSW fault zone as strike slip. Left-lateral displacement along the KSW fault zone is ~14 km, ~2-5 km greater than that of the apparent left-lateral displacement of the KSW caldera wall that lies to the northeast of the map area. The disparity in amounts of left slip may be due to the differences in extension in the NW and SE domains and along-strike slip variations.

The KSW fault zone either operates independently from or is the lateral termination of the Mormon Peak detachment. Estimates of the depth of the Mormon Peak detachment beneath the Meadow Valley Mountains place it above the brittle-ductile transition zone indicating that the Mormon Peak detachment and the KSW fault zone could interact within the brittle zone at depth.

In addition, the two faults have similar slip directions. However, no direct or causal relationship can be determined from the new data.

The NBR-CBR boundary is a wide zone with significant left slip faults that spatially coincides with the Southern Nevada seismic belt and contains transfer faults: the KSW fault zone, the PSZ, and the faults of the Timpahute lineament. Gravity data, structures at a high angle to the rift boundaries, strike-slip faults, and a topographic ramp taken in combination with the spatially coincident Southern Nevada seismic belt suggest that the NBR-CBR boundary is broad and composed of transfer faults that segment the BRP. The NBR-CBR boundary zone accommodates the differences in extension between the NBR and CBR subprovinces from Miocene through Quaternary time. Thus, the NBR and CBR subprovinces are considered distinct rift segments, even though more work needs to be done on additional structures that compose the NBR-CBR boundary zone.

### ***Eocene Conglomeratic Sediments***

U-Pb analyses of detrital zircon grains from the Ecs show that at ~39 Ma sediment was sourced from Cambrian and older quartzites. These quartzites are not exposed in the upper plate of the DT but are well documented in the upper plate of the Gass Peak thrust and others that have equivalent structural positions in the Sevier retroarc fold-thrust-belt. Thus, those thrust plates, exposed to the north and west, are the likely sediment source area. These relations suggests that in the Eocene part of the Sevier hinterland highland was proximally located.

The Ecs was deposited atop the lowest imbricate of the DT stack and in a paleo-low showing paleorelief and that Sevier-related deformation had ceased in the KSW area at the time of deposition. The spatial distribution and sediment source area of the Ecs unit suggests that the paleorelief of the Sevier hinterland is a rugged highland whose topographic maxima existed to

the N and W of the KSW area. The Ecs unit was deposited on the DT footwall suggesting that the DT plate formed a local high. The structural position of the DT suggests that the Ecs unit was deposited atop the wedge of the Sevier fold-thrust belt.

Locally, the Ecs is representative of an eastward-draining fluvial and lacustrine system and was likely part of a larger system of potentially interconnected drainages across the Sevier wedge.

Other lithologically similar deposits in similar structural and stratigraphic positions exist within the region. These rocks document an Eocene period of Sevier wedge and hinterland erosional denudation and tectonic quiescence prior to the ignimbrite flare-up.

### ***Sevier thrusts: Delamar and Meadow Valley Thrusts***

The DT and MVT are not the same thrust but part of the same imbricate stack with the DT being the highest thrust, the MVT being the middle imbricate of an imbricate stack, and an unnamed thrust being the lowest of the imbricate stack. The DT places Cambrian rock atop Devonian, the MVT places that same Devonian unit atop Pennsylvanian-Permian rock, with that Pennsylvanian-Permian rock being placed atop more Pennsylvanian-Permian rock

The DT occurs in the ranges on both sides of the KSW fault zone. In the Meadow Valley Mountains, latest Cambrian rock correlates to the DT plate in the Delamar Mountains; however, the thrust is not exposed because the DT was down-dropped along a normal fault. In the Delamar Mountains, the DT similarly is either cut out and down-dropped or reactivated by Miocene and later high-angle normal faults.

The DT is considered to be the southward equivalent to the Wah Wah system and is interpreted here to be the northward equivalent of the Dry Lake and Lee Canyon or Deer Creek thrust systems. The structural and stratigraphic relationships of the DT and MVT are consistent with thrusts southward in the Dry Lake thrust system and the Lee Canyon thrust system, all of which

occupy the structural position between major hinterland thrusts like the Wheeler Pass - Gass Peak thrusts and frontal thrusts like the Keystone and Mormon thrusts.

### ***Overprinted deformation***

Overprinted deformation provides the ability to use one deformation event to study the other, providing a more complete picture of the tectonic and deformation history of the area. In the KSW area the younger Cenozoic structures, the KSW fault zone and associated normal faults, exposed lower imbricates of the DT and obscured both the DT and MVT, but these relations provided the opportunity to use the thrust offsets to quantify the total left slip of the KSW fault zone as ~14 km. In addition, the map data revealed that Cenozoic overprinting of the Sevier-related structures did not lead to the earlier structures controlling the orientation of the majority of the younger ones.

In summary, detailed map data were used to suggest that the Cenozoic KSW fault zone is a left-lateral transfer fault that (1) separates distinct normal fault domains, (2) forms part of a broad strike-slip rift segment boundary between the NBR and CBR, and (3) offsets the DT of the Sevier belt as well as post-thrusting paleorelief and sedimentary deposits, the Ecs. The DT correlates regionally to the Wah Wah and Dry Lake thrusts which developed within the Sevier wedge. Rocks of this wedge were unconformably overlain by the Ecs, which has a maximum depositional age of ~39 Ma based on detrital zircon grains in a paleo-low adjacent to the main DT.

**Appendix A: Plate 1— Geologic Map of the Southwestern Kane Springs Wash Area**

*Plate is located in attachment one of supplemental material in ProQuest*

## Appendix B: Figures

Figure 1: Regional structure and tectonic map. Map shows part of the Basin and Range province boundaries as red dashed lines. Sevier frontal thrusts are shown in dark black lines and hinterland thrusts shown in grey lines. Major thrusts are the Canyon Range thrust (CRT), Delamar thrust (DT, this study), Dry Lake thrust (DLT), Gass Peak thrust (GPT), Golden Gate thrust (GGT), Meadow Valley thrust (MVT, this study), Mormon thrust (MT), Mount Irish thrust (MIT), Pahranaagat thrust (PT), Wah Wah thrust (WWT) and Wheeler Pass thrust (WPT). The Kane Springs Wash fault zone (KSW) is a Miocene-Quaternary left-lateral fault that cuts Sevier belt structures. The Eocene drainage divide (purple dashed line) separates drainages that drain ~E and ~W during Eocene time subparallel to the Sevier hinterland topographic maximum. The 0.706  $^{87}\text{Sr}/^{86}\text{Sr}$  initial ratio line (dashed blue line) shows the boundary between the continental lithosphere to the south and east and accreted rocks. Figure compiled from Taylor et al. (2000), Long (2012), Henry and John (2013), Arehart et al. (2013), Greene (2014), and Giallorenzo et al. (2018).

Figure 1: Regional structure and tectonic map

# Regional Geologic Map

Figure 2: Regional geologic map. Regional map of Southern Nevada and adjacent Utah showing major regional structures and localities. The Tropic-Linnet Lineament as the northern edge of the NBR-CBR boundary zone is shown by a red dotted line. The southern edge of the NBR-CBR boundary zone is shown by a black dotted line. The KSW fault south of the Caliente-Enterprise (CEZ) zone (black dotted line). Pahrangat Shear Zone (PSZ) shown with thick dark lines. Kane Spring Wash Calderas shown in long black dashed lined.

Figure 2: Regional geologic map

Figure 3: Elevations of the Basin and Range province

Figure 3: Elevations of the Basin and Range province. Figure modified from GeoMapApp ([www.geomapp.org](http://www.geomapp.org); Ryan et al., 2009). Elevations of NBR-CBR boundary zone showing an increase in average basin elevation across this zone. Basin elevations of ~1100 m (blue) are common in the CBR, while elevations of ~1600 m (tan-green) are typical of the NBR. The states NV, CA, UT, and AZ are outlined in thin black lines. The Basin and Range is outlined in thick red lines. The NBR-CBR boundary zone is outlined in a thick dashed red line where areas of E-W to W-SW topographic grain aid in defining the NBR-CBR boundary zone ally. The Kane Spring Wash (KSW) fault zone study area outline in yellow. The KSW fault zone, the Palmarazgar shear zone (PSZ) and the Timpahute lineament (TL) are shown by thick black lines (Ertan et al., 1996).

Figure 4: Bouguer gravity anomaly map of the Basin and Range. Figure modified from GeoMapApp ([www.geomapp.org](http://www.geomapp.org); Ryan et al., 2009). Bouguer gravity anomaly map overlaying topography (Kruck, 1999). The gravity anomaly near ~-37 degrees N helps define the NBR-CBR boundary zone. The areas of significant seismic activity are outlined by a thick dashed red line; these areas include the Southern Nevada seismic belt (SNSB), the Walker Lane belt (WLB), the Eastern California Shear Zone (ECSZ), the Intermountain Seismic Belt (ISB) and the Northern Arizona Seismic Belt (NASB) (Kreemer et al., 2010). The Kane Spring Wash (KSW) fault zone study area is outlined in yellow. The KSW fault zone, the Palmarazgar shear zone (PSZ), the Timpahute lineament (TL) - listed from south to north - are shown by thick black lines.

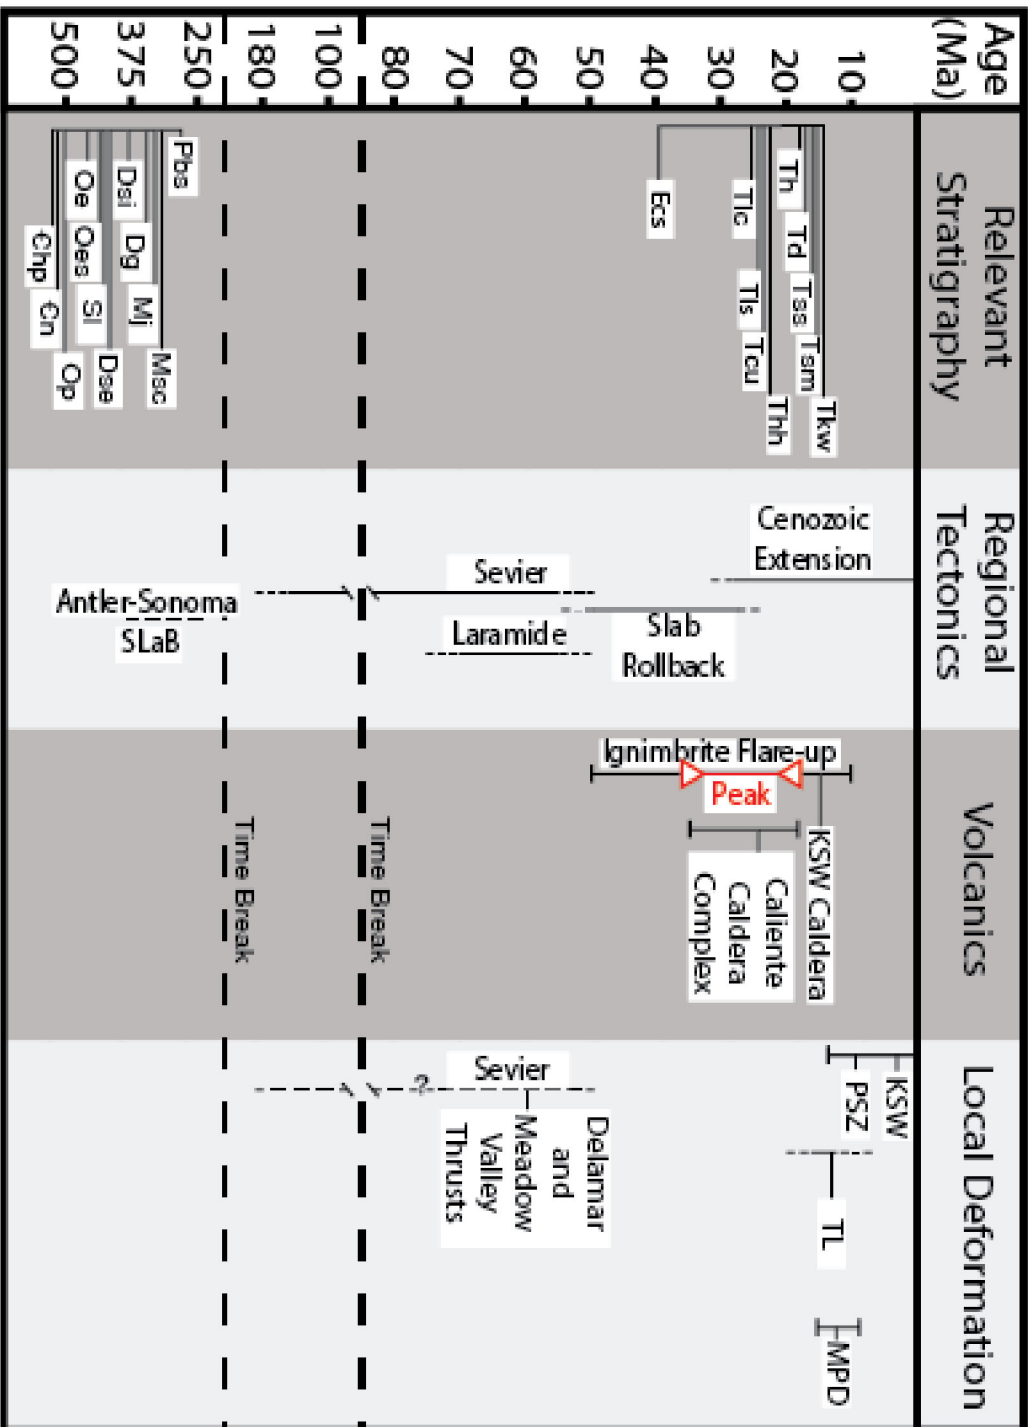

Figure 5: Timing chart. A timing chart showing the timing of major depositional and tectonic events relevant to the history of the KSW area. Unit abbreviations are the same as Plate 1, and stratigraphic columns Figure 6 and Figure 7. The peak of the ignimbrite flare-up is shown in red (Best et al., 2009; Best et al., 2013b, 2016). The timing of the Kane Springs Wash fault zone (KSW), Palrangat shear zone (PSZ), Timpanute lineament (TL), and the Moromon Peak detachment (MPD) relative to each other is shown (Pampeyan, 1993; Anderson, 1999; Felger and Beard, 2010; Bidgoli et al., 2015; Galloranzo et al., 2018; Bidgoli, 2020 personal comm.). Note deposition of the Eocene conglomeratic sediments (Ecs), relative to the Delamar and Meadow Valley thrusts.

Figure 5: Timing chart

Figure 6: Paleozoic stratigraphic column. Paleozoic stratigraphy relevant to the Kane Springs Wash area. Right side of the the stratigraphic column shows the typical weathering profile. The unit thicknesses are derived from Tschanz and Pampeyan (1970), Page et al. (1990), Scott et al. (1990), Scott et al. (1993), Pampeyan (1993), and Swadley et al. (1994).

Figure 6: Paleozoic stratigraphic column

Figure 7: Tertiary stratigraphic column. Right hand side of the stratigraphic column shows the typical weathering profile. The unit thicknesses are derived from Page et al. (1990), Scott et al. (1990), Scott et al. (1993), Pampeyan (1993), Swadley et al. (1994), Best et al. (2006), Best et al. (2013a) Best et al. (2013b), and Page et al. (1990).

Figure 7: Tertiary stratigraphic column

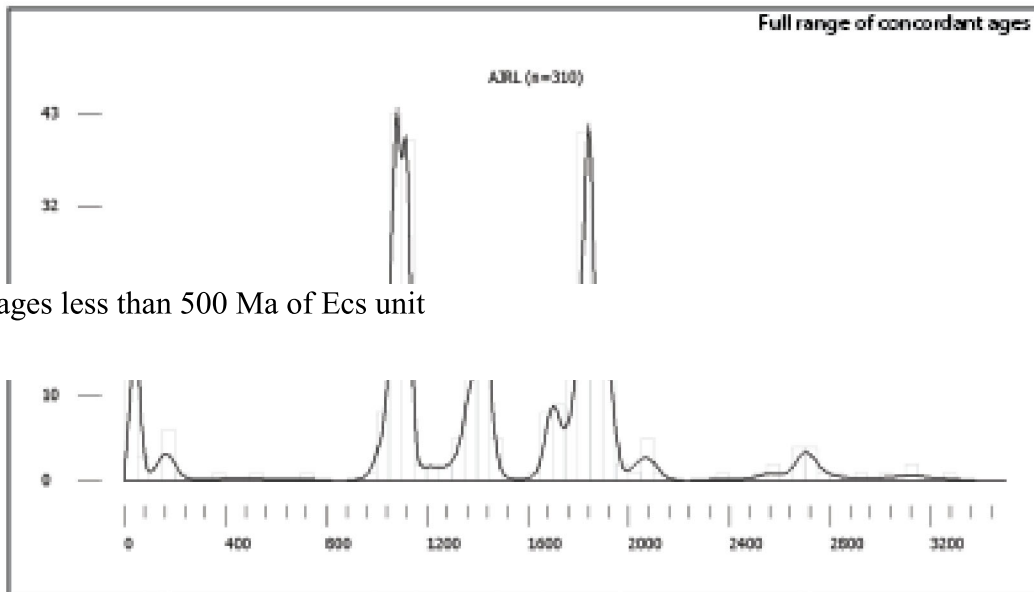

Figure 8 : Full range of concordant ages of Ecs unit. Full range of concordant ages from zircon grain samples taken from upper Eocene conglomeratic sediment unit (Ecs). Figure and data provided by T. Bidgoli (personal commun., 2020). Sample locations shown on Plate 1.

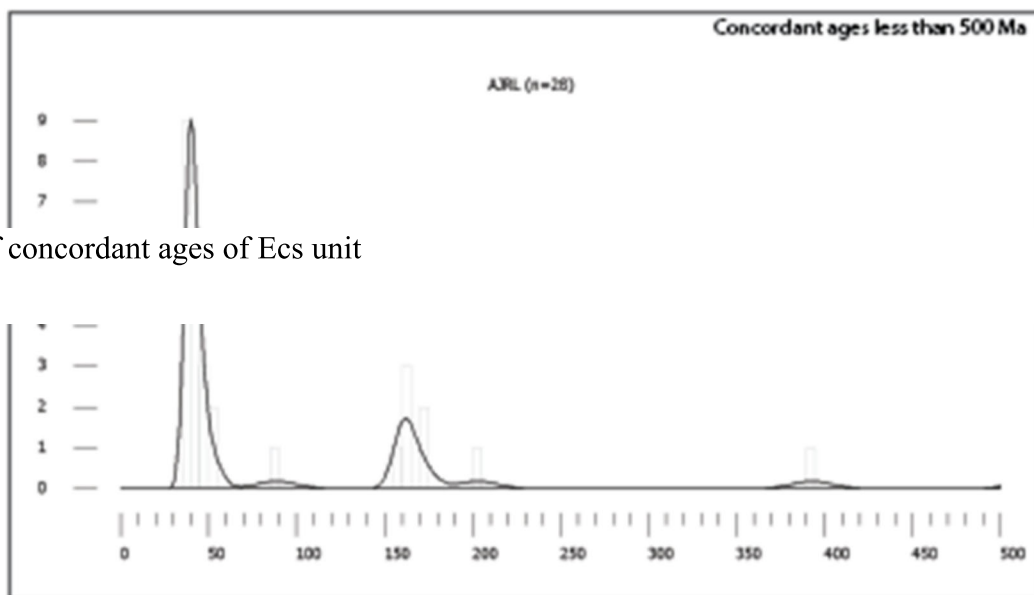

Figure 9: Concordant ages less than 500 Ma of Ecs unit. Range of concordant ages from detrital zircon grain samples taken from upper Eocene conglomeratic sediment unit (Ecs) that are less than 500 Ma. Figure and data provided by T. Bidgoli (Appendix B; personal commun., 2020). Sample locations shown on Plate 1. Note late population at 39 Ma.

Figure 11: Detrital kernel density estimation

Figure 10: Detrital zircon concordant age plot

Figure 10: Detrital zircon concordant age plot. Concordia diagram that shows the maximum depositional age ( $39.0 \pm 0.3$  Ma) of detrital zircon grain samples taken from upper Eocene conglomeratic sediment unit (Ecs). Figure and data provided by T. Bidgoli (personal commun., 2020). Sample locations shown on Plate 1.

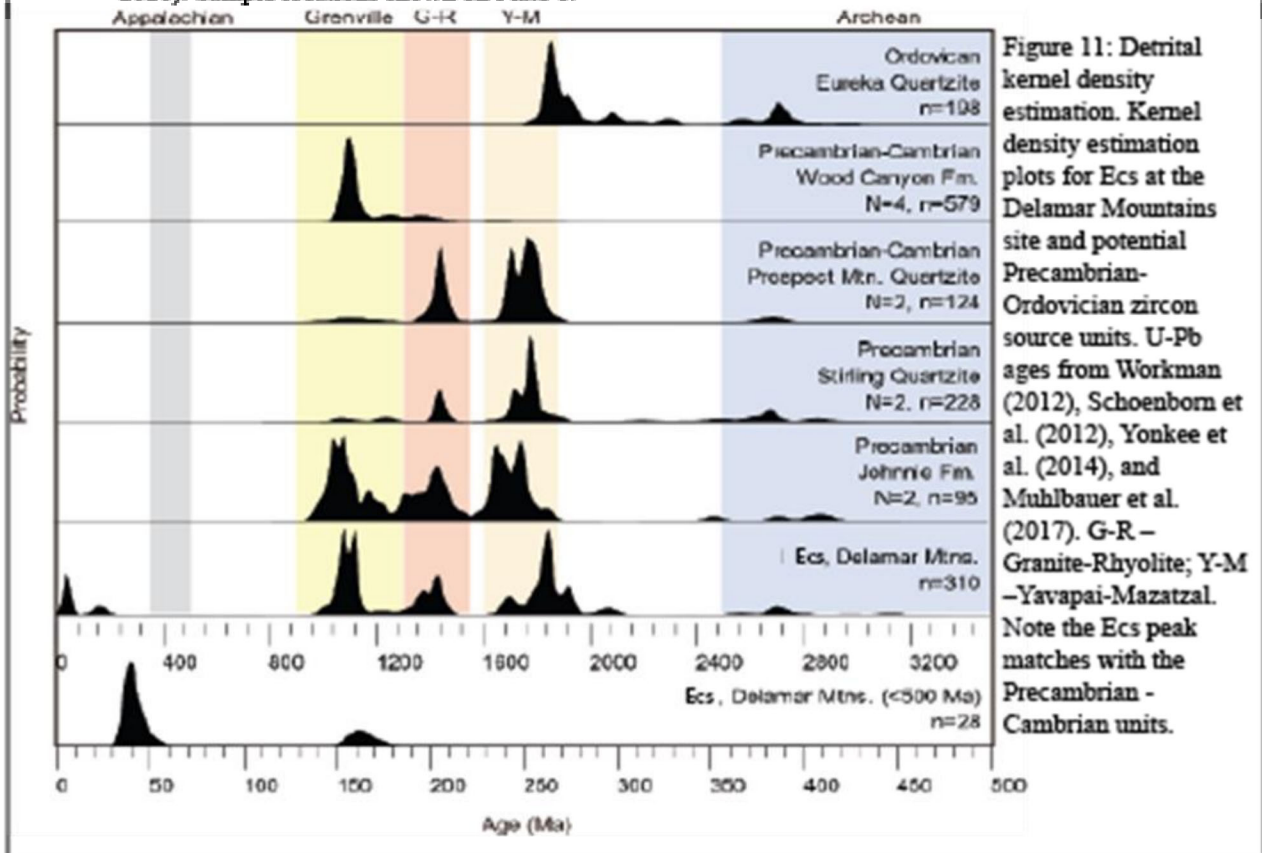

Figure 11: Detrital kernel density estimation plots for Ecs at the Delamar Mountains site and potential Precambrian-Ordovician zircon source units. U-Pb ages from Workman (2012), Schoenborn et al. (2012), Yankee et al. (2014), and Muhlbauer et al. (2017). G-R – Granite-Rhyolite; Y-M –Yavapai-Mazatzal. Note the Ecs peak matches with the Precambrian - Cambrian units.

Figure 12: Fault map, rose diagrams and stereographs

Figure 13: Diagrammatic maps of development through time

Figure 13: Diagrammatic maps of development through time. The stepwise block diagram showing a diagrammatic progression of the development of the Kane Springs Wash (KSW) area from the end of Sevier time after the deposition of the Eocene conglomeratic sediments (Ecs) unit. At ~39 Ma (A) the map shows, the Cambrian (C) upper plate of the Delamar thrust (DT) over the Devonian (D) upper plate of the Meadow Valley thrust (MVT) and the lowest Pennsylvanian-Permian lower plate overlain by the Ecs. Second (B) is showing the KSW fault area after the collapse of the KSW Caldera in which the caldera wall is shown in a thick dark line as a fault with hachures on the interior of the KSW caldera. Thirdly (C), The early development of the KSW fault zone, shown with diagrammatic structural relationships developing, such as Fault GB, note the DT is no longer exposed at the surface but likely exists at depth with the development of the KSW fault zone. Finally (D), the current development of the KSW fault zone, with greater slip than in C, is shown with faults that transfer slip onto it and with quaternary valley fill omitted to clarify the diagrammatic structural relationships.

Figure 14: Paleotopography illustrated from map relationships

Figure 14: Paleotopography illustrated from map relationships. Figures show critical stratigraphic relationships illustrating former paleotopography as onlapping or buttressing of the Eocene conglomeratic sediments (Ecs) and ash-flow tuffs over the Meadow Valley thrust (MVT) and Paleozoic rocks. Note the Delamar thrust (DT) is not overlain by the Ecs. These relations suggest significant paleorelief along the sub-Tertiary unconformity. Unit labels are the same as in Figures 6 and 7

A. In the Meadow Valley Mountains the Ecs unit is overlain by ash-flow tuffs that together drape over the upper and lower plate of the MVT. Note that the Ecs unit does not completely overlie the upper plate of the MVT such that the Dg formed the upper part of a paleohill.

B. In the Meadow Valley Mountains, the uppermost and youngest ash-flow tuff (Tkw) banks against former topographic highs of the upper plate of the DT composed of Cn and are down-dropped along a normal fault adjacent to lower tuffs.

C. In the Delamar Mountains, the Ecs unit and overlying ash-flow tuffs overlie the lowest imbrication of the MVT and buttress against its upper plate. Note the draping of the ash-flow tuffs over the Cambrian rocks in the upper plate of the DT on the left side of map.

## Appendix C: Detrital Zircon Data Tables from T. Bidgoli (2020)

The detrital zircon grains analyzed are double-dated using the U-Pb and (U-Th)/He methods to determine depositional age and provenance (Campbell et al., 2005; Reiners et al., 2005; Dickinson & Gehrels, 2009, 2010; Saylor et al., 2012). A total of 347 grains were picked from samples collected from deposits that overlie the lowest imbricate of the MVT for U-Pb laser ablation inductively coupled plasma mass spectrometry analysis at the University of Kansas, Isotope Geochemistry Laboratory. Analysis of this large number (~300) of grains ensures that the entire range of zircon age populations are captured and can undergo statistical tests required to provide robust data (Sircombe, 2000; Fedo et al., 2003; Jackson et al., 2004; Vermeesch, 2004; Andersen, 2005; Pullen et al., 2014; Saylor & Sundell, 2016).

## Curriculum Vitae:

### Andrew Reid

702-720-4467 (Google Voice) | andrew.reid27@gmail.com

**Education**            **M.S., Geology**, University of Nevada – Las Vegas, (Current)  
Area of Focus: Structural Geology and Tectonics  
**Thesis:** *Mesozoic Sevier Thrusts Overprinted by Miocene-Quaternary Left-Lateral Deformation: Structures and Tectonism of The Kane Springs Wash Region, Nevada*, Advisor: Wanda J. Taylor (Approved Proposal Available)

**B.S., Geology**, University of Nevada - Las Vegas, August 2018.  
**Research:** *Prospectivity of Carbonatites in the Great Basin*, Advisor: Simon Jowitt,  
*Modified Slab Deformation of Tiger's Eye Quartz*, Advisor: Pamela Burnley

**B.S., Psychology**, University of Nevada - Las Vegas, August 2013.

**Areas of Focus**        Structural Geology, specifically structural field methods and analysis. Geospatial analysis and prospectivity modeling using geophysical, geochemical, aeroradiometric data and spectral imagery. High-pressure and high-temperature rock deformation experimentation.

**Positions**    March 2022 – Present        **Geologist 1 – Underground Mine Geologist**  
Barrick Gold – Nevada Gold Mines

**Responsibilities:** My work focuses first, and foremost, on workplace safety to carry out daily underground geological work with technical expertise. Daily work includes lithological mapping, structural mapping, inspecting stopes, collecting muck samples and chip sampling, drill core logging, geological interpretation and modelling. This work is in collaboration with technical and operational teams to ensure timely and effective ore control activities and meet monthly production and development plans while adding value to overall mining operations. Commonly required to carry out special projects including geological reviews, preparation of reports.

May 2021 – March 2022    **Staff Geologist**  
Southwest Geotechnical

**Responsibilities:** My work focused on special inspections of soil stability of foundations in new and old construction sites. Reports are directly sent to Project Manager, typically a geotechnical engineer, and are used to provide third-party inspections of grading sites. Sample collection and use of field instruments required. Driving to new sites and developments in vehicle.

Aug. 2018 – May 2021    **Graduate Teaching Assistant**  
University of Nevada, Las Vegas  
Department of Geoscience

**Responsibilities:** My research focused on developing map products and other field data to better understand the tectonic development of the

Basin and Range province in the western US, emphasizing overprinted deformation. My duties include teaching laboratory courses and methods in structural geology, and advanced field geology with an emphasis on tectonics and field methodology.

Jun. 2019 – Aug. 2019 **Contract Geologist**  
Barrick Gold Exploration

**Responsibilities:** My work focused on the management and QA of legacy geologic data including drill log information, geochemical and metallurgical assays. My primary duty was to determine the viability and duplication of legacy data obtained from purchased junior exploration companies.

Feb. 2018 – Aug. 2018 **Geospatial Information Systems Technician**  
Desert Research Institute  
Division of Earth and Ecosystem Sciences with Lynn Fenstermaker

**Responsibilities:** My work focused on the remote sensing of vegetation, soils, rocks, to monitor ecosystems, perform habitat studies, and land coverage dissemination using multispectral and hyperspectral imagery from aerial and satellite platforms for clientele. Other projects included the generation of free-standing databases with important land use and agricultural information to disseminate to clients to enhance their analytic capabilities. I created workflows to accomplish the goals of the given study and so methodology is repeatable in future work. Software includes QGIS, ArcGIS, and ENVI.

Jul. 2017- Aug. 2018 **Research Assistant**  
Nevada Rock Deformation Laboratory  
University of Nevada – Las Vegas  
Laboratory of Dr. Burnley

**Responsibilities:** My work focused on performing experiments in the Single Piston Griggs Apparatus. I performed high-pressure high-temperature experiments, sample preparation, machining sample assemblies, creating thin-sections for post-deformation analysis, mineral synthesis, powdered XRD analysis of synthesized minerals, Laboratory equipment and facilities maintenance.

Aug. 2015 – Jul. 2016 **Registrar Analyst**  
University of Nevada, Las Vegas  
Office of the Registrar

**Responsibilities:** My duties included the construction and maintenance of the curriculum and course database with operative conditional SQL statements, garnering compliance from academic departments to adhere to academic calendar deadlines, troubleshooting curriculum and scheduling changes to meet academic department goals while adhering to academic standards set by the Nevada System of Higher Education. Maintenance of social media and website data for the Office of the Registrar. Generating new efficient workflows that ensure a timely and effective processing of all incoming space management requests by academic departments and intraoffice needs.

Aug. 2013 – Aug. 2015 **Enrollment Counselor**

University of Nevada – Las Vegas  
Enrollment Services Center

**Responsibilities:** I was responsible for assisting students with the navigation and compliance of university policy, the evaluation of applications for in-state residency, troubleshooting international student procedures, creation and operation of social media outreach initiative, updating the outward facing MyUNLV system in compliance with UNLV reprographic, creating new workflows that and procedural manuals for modernizing incoming requests that allow for transparency and approachability of office procedures.

<b>Awards</b>	Fall 2019	Bernada French Scholarship Recipient
	April 2017	3 <sup>rd</sup> Place Undergraduate GIS Poster, UNLV 2017 Geosymposium
	May 2013	Millennium Scholar Nevada GEAR UP Scholar EPSCoR Nevada Discoveries Magazine Student Highlight
