ABSTRACT

Physiology and Genetics of Starvation-selected *Drosophila melanogaster*

By

Christopher M. Hardy

Dr. Allen G. Gibbs, Examination Committee Chair
Associate Professor of Biological Sciences
University of Nevada, Las Vegas

In nature, organisms have evolved to survive in stressful environments. This has driven organisms to adopt a wide range of unique adaptations. Investigating the mechanistic basis of these adaptations is an important tool for discovery that has led to major advances in science and medicine.

We study how organisms survive life without food, or starvational stress. Environmental stressors have shaped the quantity and quality of food sources across the globe. This has led to vast differences in the ability of some organisms to tolerate starvation over others. Many researchers have used *Drosophila melanogaster* as a model to study global patterns of variation in starvation resistance. We complement this approach by experimentally evolving populations of *D. melanogaster* to become starvation resistant in the laboratory.

Starvation-selected *D. melanogaster* are ~3-4 times more resistant to starvation than their unselected controls. They do this primarily through an increase in stored lipids. Excess fats provide an abundant source of energy that can be metabolized to fuel all aspects of life when nutrients are scarce. However, the enhanced ability to survive starvation and store high levels of body fat comes at a cost to many other aspects of fitness. These evolutionary tradeoffs include a developmental delay, decreases in fecundity, metabolic

rate, activity levels and flight performance and disrupted sleeping patterns. Because some of these phenotypes are characteristic of metabolic disorder in mammals, we use starvation-selected *D. melanogaster* as a model to study the physiological and genetic basis of obesity.

Obesity is one of the leading risk factors for heart disease. Here, we tested the hypothesis that heart function is an evolutionary tradeoff with starvation resistance. We found that the hearts of starvation-selected *D. melanogaster* were dilated and poorly contractile- a condition known as dilated cardiomyopathy. We observed that heart dysfunction was highly correlated with increased fat tissue located between the heart and dorsal cuticle. The excess tissue physically altered the gross anatomical placement of the heart. Further experiments led us to suspect that this physical interference was the primary source of dysfunction. During these analyses we also discovered that the starvation-selected flies avoided lipotoxicity in the heart. Lipotoxicity is a common mechanism of obesity-associated heart dysfunction where excess lipids are ectopically stored within the myocardium. Instead, we found that the fat body of the starvation-selected flies contained very large lipid droplets whose estimated increase in volume could account for the ~2-fold whole body increase in total lipids. We hypothesize that the increased lipid droplet volume in the fat body of the selected populations is an adaptive response to increase the amount of stored lipids for starvation resistance, while limiting the harmful effects of lipotoxicity in peripheral tissues.

We were next interested in exploring the genetic basis of adaptation to starvation selection. To do this, we resequenced genomic DNA from the starvation-selected populations and their fed controls after 83 generations of starvation-selection. In total we

found 1,046,373 polymorphic sites, with many loci diverging between selection treatments. We found evidence for genetic heterogeneity between the replicates of the selected populations. The relative genetic differences between the starvation-selected replicates were physiologically relevant, as they correlated with differences in starvation resistance. We surveyed the genome for signatures of selection and found many large troughs in heterozygosity that approached fixation within the selected populations. These regions were variable across selected replicates, consistent with hard selective sweeps. In addition to these extreme regions of reduced heterozygosity, we found many locations across the genome that differed in allele frequency between selective treatments. To identify which regions were divergent due selection, we generated a novel algorithm to filter the effects of genetic drift from the dataset. After applying our drift filter, we mapped SNPs within each population to sets of genes. We focused on the most conserved mechanisms across replicates and found 1,453 genes, which were associated with a SNP under selection in all three replicate populations. These genes were enriched for many biological processes, including many associated with the evolved physiologies of the starvation-selected populations, including regulation of metabolism. Many of the candidate genes were found within the insulin and adipokinetic hormone-signaling pathways. 542 of the candidate genes are previously uncharacterized in *D. melanogaster*. These genes can be functionally validated for their potential role in starvation resistance and lipid metabolism in future studies.

Finally, we performed experiments to investigate the mechanistic basis of the ~24 hour delay in larval development in the starvation-selection populations. This delay provides starvation-selected larva more time to feed and accumulate lipids that are then

used for adult starvation resistance. In *D. melanogaster* a large pulse of the steroid hormone 20-hydroxyecdysone (20E) occurs near the end of larval development. This late-larval 20E pulse initiates a transcriptional cascade that commits the animal to pupariation. Our preliminary data suggest that the developmental delay in the starvation-selected populations is the result of a delay in the timing of the 20E pulse. If this hypothesis is correct, 20E-induced gene expression should be similar in the selected populations and their unselected controls at the onset of pupariation. To test this we resequenced the transcriptome of the larval fat body in the selected populations and their unselected controls during and after the onset of pupariation. We found that a large fraction of differentially expressed genes had similar patterns of expression between samples of the selection treatments. These data suggest that 20E-signaling functions similarly in both groups, just at a different time point in response to selection. However, there was a smaller, yet significant number of genes which were differentially expressed in response to selection. Furthermore we found that expression profiles differed among replicate populations of the starvation-selected line. Taken together, these results suggest that selection may have altered the timing of the late-larval 20E pulse, as well as the tissue-specific response to the 20E signal. These findings provide further insight into the mechanistic basis of the ~24 hour delay in larval development, which will be explored in future studies.

.

ACKNOWLEDGMENTS

I am extremely appreciative for the tremendous amount of help that went into making this work possible. First and foremost I would like to thank my family. From an early age they taught me to work hard, be independent and think critically. However, most importantly, they taught me to love exploring the world. My family has grown during my time at UNLV to include my wife, Christensen Hardy and her beautiful family. My entire family has consistently, tirelessly and lovingly gone out of their way to allow me to pursue this work to the best of my ability. I am forever grateful.

From an academic standpoint I am thankful to both Michael Rose and Molly Burke, who first inspired me to pursue biology and mentored me along my path to graduate school. Through them I met my academic advisor, Allen Gibbs. Allen is a brilliant scientist. He is an even better person. He taught me to write short, declarative sentences. He never yelled at me more than he had to when I would set off the fire alarm, and he was always there to open my office door when I locked my keys inside. He gave me the freedom to study anything I was interested in and was *never* too busy to offer advice, or help me figure out a problem in the lab. I am honored to have worked with him over the past six years and know that I will never find a mentor that is more dedicated to his students than Allen.

I have repeatedly been overwhelmed by the support I have received from the science community. Often times if I had a question that could not be addressed with the resources at UNLV I would blindly reach out to other researchers in the field. Specifically, I would like to thank Ryan Birse and Rolf Bodmer from the Sanford Burnham Institute for teaching me new methods and lending me their facilities to perform the work. I would also like to thank Matthew Wolf from the University of Virginia School of Medicine and Lin Yu

from the Duke School of Medicine for their generous contribution of time and resources.

Finally I thank Logan Everett from North Carolina State University for helping me develop computational solutions to improve our experiments.

Here at UNLV there have been countless people who have helped guide and support me through my graduate career. First I would like to thank my graduate committee. They held me to a high standard, which greatly improved the quality of the work. Outside my committee I would like to thank Mira Han who helped me develop my ideas for the genomic work and provided excellent feedback. I have also been supported by many other graduate students at UNLV. In particular, I would like to thank friend/collaborator Katie Lantz who was always there to help with experiments and keep me moving forward.

Science makes big progress in small, incremental steps. Thank you to everyone that has helped each step of the way.

DEDICATION

To my wife, Christensen-

I wouldn't be here without you,

And I wouldn't want to be anywhere without you.

CHAPTER 1

LABORATORY SELECTION FOR STARVATION RESISTANCE IN *DROSOPHILA*

MELANOGASTER: OBESITY AT WHAT COST?

1.1 Experimental evolution is a powerful tool to test evolutionary theory and study how organisms adapt to stressful environments.

In nature, organisms must constantly adapt to a wide variety of stressors, which are dynamic and largely unpredictable. Adapting to these changing environments takes place on many different timescales ranging from daily or seasonal shifts in physiology to long-term evolution by natural selection. Evolution has generated a wide range of variation between organisms that allow them to thrive even in extreme environments. Examples from nature are diverse, from deer mice surviving in severely hypoxic mountain ranges (Carey et al. 2012) to thermophilic bacteria in hydrothermal vents (Brock and Freeze 1969). Investigating how organisms adapt to extreme environments is a powerful tool that has led to important advances in modern sciences and medicine. The long history of studying uniquely adapted organisms was popularized by the Danish physiologist, August Krogh, who stated, “For many problems there is an animal on which it can be most conveniently studied” (Krebs 1975). Application of the Krogh Principle in practice has led to important scientific advances including the use of highly metabolic pigeon breast muscle to uncover the tricarboxylic acid cycle (Krebs and Johnson 1980), the isolation of heat-stable DNA polymerase from the thermophilic bacterium *Thermus aquaticus* to facilitate

polymerase chain reaction (Chien et al. 1976) and the use of giant squid axons to determine the ionic basis of action potentials (Hodgkin and Huxley 1952).

A complimentary approach to studying uniquely adapted organisms in the wild is to perform evolution experiments in the laboratory, where environmental stresses can be mimicked by an investigator under highly controlled, replicated designs (Bennett 2003; Garland and Rose 2009). In such an experiment, a founding population is established then subjected to either an environmental stress or a control condition, which are handled in parallel for many generations. Populations exposed to selective pressures may then adapt and evolve mechanisms that enhance their fitness in the novel environment. Traditionally, experimental evolution has been implemented to both test theories of evolution and investigate the physiological basis of adaptation to novel environments (Garland and Rose 2009; Kawecki et al. 2012). Because these types of studies can be highly replicated, it is possible to distinguish random stochastic processes such as genetic drift from conserved mechanisms of evolution, which are difficult to differentiate in natural populations. Although in theory experimental evolution can be performed on any population, practical considerations have limited these studies to organisms with relatively short generation times and low cost of maintenance. Interpretations of these experiments are further limited by low population sizes and number of generations compared to macroevolutionary processes in the wild. Despite these limitations, evolution experiments afford the opportunity to directly test predictions and hypotheses derived from evolutionary theory to address a wide range of questions on the repeatability of evolution, mechanisms of speciation, life history tradeoffs and the maintenance of variation by disparate evolutionary

processes (i.e. genetic drift, mutation rates, ect.: reviewed in Kawecki et al. 2012 and the references therein).

Because of the dynamic nature of evolution, *a priori* expectations for adaptive outcomes in selection experiments are often misguided as organisms may adopt a variety of unanticipated solutions (Bennett 2003; Garland and Rose 2009). In many cases experimental selection generates biological novelty, resulting in organisms which are functionally enhanced over their unselected controls or similar organisms in nature (Bennett 2003; Garland and Rose 2009). Understanding the mechanistic basis of these improvements has the potential for translational impact (e.g. extended longevity in *Drosophila*: Rose 1984; improved running performance in mice: Garland Jr. 2003). Some of the best examples come from evolution experiments in microbes, which can evolve quickly and be maintained in large population sizes. Such studies have played important roles in vaccine development, particularly in serial passage experiments where pathogens are introduced into a novel species and allowed to adapt across multiple passages. After several passages the virulence of the pathogen increases as it adapts to the new host. These adaptations incur evolutionary cost, leading to attenuated pathogenicity in the former host. This approach has been used in the development of some live vaccines (Ebert 1998).

The capacity for experimental evolution to drive discovery has been further enhanced by the increased accessibility of genetic sequencing over the past decade. Some early studies were able to track the trajectories of adaptive alleles over the course of natural selection by looking at multiple genetic markers across a single chromosome in *Drosophila* (Teotónio et al. 2009). Since that time, exponential improvements in deep sequencing technologies have driven down costs and made whole-genome sequencing of

organisms under selection a powerful new paradigm in experimental evolution. In one study, a malaria inducing parasite, *P. chabaudi*, was selected for drug resistance against an array of common malarial medications (Hunt et al. 2010). The evolved strains were fully sequenced and genes that confer drug resistance were proactively identified before any such mutation had occurred in nature. This type of study could allow health industries to proactively develop diagnostic tests and therapeutic interventions.

Over the past several years, studies combining experimental evolution with whole genome sequencing have been called “Evolve and Resequence” experiments (E&R; Turner et al. 2011). While E&R experiments have been performed in many organisms (Johansson et al. 2010; Rubin et al. 2010; Parts et al. 2011; Kelly et al. 2013; Beissinger et al. 2014; Burke et al. 2014), they have paired particularly well with the *Drosophila* model largely due to its short generation time, fully sequenced reference genome and the wealth of genetic resources. This paradigm has been used to address fundamental questions about the evolutionary patterns of adaptation and to uncover the genetic basis of evolved physiologies. To date, many E&R experiments have been performed in *Drosophila*, selecting for a variety of different traits including hypoxia tolerance, longevity, courtship song, body size, development time, desiccation resistance, high temperature and resistance to both the parasitoid *Asobara tabida* and the *Drosophila C* virus (Burke et al. 2010; Turner et al. 2011; Zhou et al. 2011; Orozco-terWengel et al. 2012; Remolina et al. 2012; Turner and Miller 2012; Jalvingh et al. 2014; Martins et al. 2014; Kang et al. 2016).

While the field will continue to improve by refining design parameters to increase the power to detect rare variants (Baldwin-Brown et al. 2014; Kessner and Novembre 2015), studies in pre-existing evolved populations have made several exciting discoveries.

In particular they have found complex patterns of adaptation. For instance, most E&R studies in *Drosophila* have found that selection acts on standing genetic variation rather than *de novo* mutations (Burke 2012; Long et al. 2015; but see Kang et al. 2016). This leads to large numbers of polymorphisms that shift in frequency in response to the evolutionary treatment. However, the trajectories of adaptive alleles may vary across evolutionary time. For instance, one E&R study found that while some alleles rose quickly and plateaued, others steadily increased across generations (Orozco-terWengel et al. 2012). In any case, as an advantageous allele sweeps towards fixation within the population, it pulls along linked regions of flanking DNA (Smith and Haigh 1974). This process is known as genetic hitchhiking, and it results in localized areas of reduced heterozygosity across the genome. Genome-wide scans of heterozygosity are therefore useful in identifying signatures of selective events. E&R studies have identified genes in close proximity to these signatures of selection and in some instances discovered pathways involved in adaptation (Burke et al. 2010; Turner et al. 2011; Zhou et al. 2011; Orozco-terWengel et al. 2012; Remolina et al. 2012; Turner and Miller 2012; Jalvingh et al. 2014; Martins et al. 2014). An important limitation of this approach is that linkage disequilibrium (LD) has been found to increase in experimentally evolved populations of *Drosophila* (Teotónio et al. 2009; Franssen et al. 2015). High LD may artificially inflate the number of genetic variants associated with selection. Fortunately, there are many genetic tools within the *Drosophila* research community that can be used to functionally validate candidate loci.

Identifying the genetic basis of complex traits is a long-standing goal for many scientific fields and E&R studies will certainly be a powerful tool of discovery in future efforts. These studies will continue to achieve greater resolution by using larger population

sizes, increasing the number of evolutionary replicates, sequencing individual organisms at greater depths and improving techniques to functionally validate putative loci. To date, E&R studies are only scratching the surface of what will be possible as techniques improve and experimental evolution is paired with other “omics” methodologies. For instance, RNA-sequencing can be used on experimentally evolved populations to study how adaptive alleles lead to functional changes in gene expression within specific tissues. Furthermore, chromatin immunoprecipitation sequencing (CHIP-seq), can be used to test how the functional organization of the genome may respond to selection. These approaches will offer new insights into how organisms respond and adapt to evolutionary pressures on the cellular level. This will improve our ability to address fundamental questions of how organisms adapt to stressful environments.

1.2 Laboratory selection for starvation resistance in *Drosophila* shifts energetic homeostasis, leading to an obese phenotype with associated evolutionary tradeoffs.

Acquisition, storage and utilization of nutrients are fundamental processes of life, required to generate the energy necessary for development, maintenance and reproduction. However, nutritional resources are constantly changing in the wild as environmental stressors shape the quantity and composition of available food. When energy resources become scarce, organisms may adapt by increasing energy storage, decreasing energy utilization or lowering the amount of energy required to survive (Rion and Kawecki 2007; Gibbs and Reynolds 2012). These adaptations affect biological decisions on when and where to divert energy resources, which ultimately has a large impact on fitness. This makes the underlying processes subject to natural selection, which has led to evolved differences in the ability of organisms to survive starvation. Understanding the nature of energy resource allocation and how organisms cope with dietary stress is a topic of considerable interest to evolutionary physiologists and has been widely studied in *Drosophila*.

In natural populations extensive variation in starvation tolerance exists both within and among species of *Drosophila* across the globe (van Herrewege and David 1997; Gilchrist et al. 2008; Sisodia and Singh 2010). The differences in the ability to survive starvation between species can be quite dramatic. For example, *D. sechellia* from the tropical African Island of Seychelles can survive only a day without food, whereas *D. arizonensis*, which are endemic to the Sonoran Desert in the southwest United States, can live just over a week (van Herrewege and David 1997). Intraspecies differences are generally not as pronounced, however when species are distributed across a wide

geographic range, adaptation to local environments may drive differentiation. For example, French and Congolian populations of *D. melanogaster* were shown to differ ~1.67 fold in starvation survival (van Herrewege and David 1997). Regional differences in starvation resistance are likely genetic as hybrids of *D. melanogaster* from diverse habitats display intermediate levels of starvation resistance (Kennington et al. 2001). Despite intensive efforts to understand the environmental factors that influence the evolution of starvation resistance, there is still no clear explanation for the geographic patterns of variation observed in *Drosophila* (Gibbs and Reynolds 2012).

Experimental evolution for starvation resistance

In order to better understand the physiological basis of adaptation to starvation, many studies have simulated starvational stress in the laboratory and evolved populations of *D. melanogaster* to become starvation resistant (Rose et al. 1992; Harshman and Schmid 1998; Reynolds 2013). Because starvation resistance in *D. melanogaster* is extremely variable and highly heritable, adaptation occurs rapidly (Service and Rose 1985; van Herrewege and David 1997). Within as few as 5-10 generations, starvation survival in the selected populations significantly increases over the unselected controls (Rose et al. 1992; Harshman and Schmid 1998). Over many generations selection greatly exaggerates this difference, allowing some populations to survive 3 to 4 times longer without food (Chippindale et al. 1996). This amounts to an absolute starvation survival duration of ~220 hours, which is well outside the ~60-110 hour range measured from natural populations of *D. melanogaster* (van Herrewege and David 1997; Karan et al. 1998).

A common adaptation to starvational stress in both laboratory selection experiments and in wild populations is to increase the amount of stored lipids (Chippindale et al. 1996; van Herrewege and David 1997; Harshman et al. 1999; Schmidt et al. 2005; Ballard et al. 2008; Sisodia and Singh 2010; Schwasinger-Schmidt et al. 2012; Goenaga et al. 2013; Aggarwal 2014). Lipids are critical for surviving starvation, as they are more energetically dense than proteins and carbohydrates and are mobilized under chronic conditions to supply the energy required for survival (Marron et al. 2003; Lee and Jang 2014). The overall lipid content in starvation-selected populations is much higher than typically found in nature and may increase as many as 3-4 times over unselected control populations (Chippindale et al. 1996; Gibbs and Reynolds 2012). These evolved differences in body fat composition are primarily due to an increase in the amount of triglycerides (TG) and not other major classes of lipid molecules (Harshman et al. 1999; Schwasinger-Schmidt et al. 2012). The overall increase in stored TGs correlates with differential activity of several enzymes associated with lipid biogenesis (Harshman et al. 1999). This indicates that starvation selection may act on variation involved in controlling metabolic homeostasis.

In addition to increasing energy storage, adaptation to starvational stress may also include a decrease in energy utilization (Gibbs and Reynolds 2012). *Drosophila* species differ in their starvation resistance per microgram of lipid, which suggests that some species may have evolved mechanisms to utilize their lipid resources more efficiently than others (Sharmila Bharathi et al. 2003). One potential mechanism to decrease energy expenditure would be to reduce metabolic rate. This is a common physiological response to acute starvation in *Drosophila* (Djawdan et al. 1997). However, the effect of laboratory

selection for starvation resistance on metabolic rate remains unclear (Gibbs and Reynolds 2012). While some studies suggest that selection reduces the mass-specific metabolic rate per fly, the effect is abolished when the mass of the non-metabolically active lipids are removed from the equation (Djawdan et al. 1997; Harshman et al. 1999). Others have been unable to replicate these findings, reporting no difference in metabolic rate per fly (Harshman and Schmid 1998). In some instances, the effects of starvation-selection on metabolic rate differed between the replicated populations under selection within the same experiment (Baldal et al. 2006). This study by Baldal et al. found that males from some replicate starvation-selected populations had even evolved a slight *increase* in metabolic rate (Baldal et al. 2006).

In addition to a reduction in metabolic rate, energy utilization could be decreased by adaptations that disrupt locomotion or reduce physical activity. However these data have also varied by experiment. While one study reported that starvation-selected flies were ~3 times less active than their controls (Williams et al. 2004), another found only a non-significant trend towards lower activity levels (Schwasinger-Schmidt et al. 2012).

The ambiguous results from these studies on energy utilization may be the result of variations in experimental design and the evolutionary history of the founding populations. For example, genetic variation in the founding populations of each experiment may have predisposed selection to act on alternative adaptive pathways, some of which may have led to phenotypes of reduced energy utilization. Furthermore, each experiment differed in the strength of selection and the number of generations in which it was imposed. These differences in experimental design could have impacted the evolutionary trajectories of alleles involved in energy homeostasis. However, the experiments described here only

sampled phenotypes after a relatively low number of generations of selection. It is possible that genetic variation associated with energy storage evolves quickly, while adaptations to reduce energy utilization are a more long-term evolutionary response. This hypothesis could explain why increased lipid storage is commonly observed in starvation-selection experiments, while reduced metabolic rate and physical activity are more equivocal. There is evidence to support that energy storage may be a “quick” adaptive phenotype in natural populations of *Drosophila*. For instance, *Drosophila* evolve quickly in response to selective pressures imposed by seasonal variation, which can drive rapid allelic change (Bergland et al. 2014). Studies have found naturally occurring polymorphisms in key metabolic genes that affect lipid storage and starvation resistance, which fluctuate seasonally and directionally across latitudinal clines (Paaby et al. 2010; Paaby et al. 2014). When these natural polymorphisms were crossed into a wildtype genetic background, they led to significant changes in lipid weight and starvation resistance (Paaby et al. 2014). Energy storage may then be affected by alleles with relatively large effect sizes that may oscillate quickly within a population. This could explain how starvation resistance and lipid weight evolve in as few as 5-10 generations in starvation-selection experiments (Rose et al. 1992; Harshman and Schmid 1998). The phenotypes associated with energy utilization may be more genetically diverse with smaller effect sizes, which would be driven by long-term environmental pressures. Tracking the evolution of these adaptations over a longer evolutionary time frame may provide further insight in future starvation-selection experiments. Regardless of the underlying evolutionary forces, starvation-selected *Drosophila* consistently adapt through profound shifts in energetic homeostasis, highlighted by large increases in stored fats.

Evolutionary tradeoffs associated with starvation resistance

Lipids are a vital resource to survive periods of low nutrient availability in the wild. However, as energy resources are diverted towards lipid storage, energy needed for life history traits such as reproduction, development or longevity may be reduced. This can lead to evolutionary tradeoffs, where starvation resistance is gained at a cost to other important fitness parameters.

In *Drosophila* energy stores are largely accumulated throughout larval development and stored in larval fat cells. These resources are required for the growth of developing tissues during metamorphosis and persist throughout the first several days of adult life (Gibbs and Reynolds 2012). In the young adult fly, larval fat cells will undergo programmed cell death and release energy which may be used to promote reproduction or to resist starvation in nutrient poor environments (Aguila et al. 2007; Aguila et al. 2013). Selection for starvation resistance commonly leads to a delay in larval development (Chippindale et al. 1996; Harshman et al. 1999). This delay increases larval feeding time, leading to the acquisition of greater energy stores that can be used for adult starvation resistance (Chippindale et al. 1996; Harshman et al. 1999). Indeed, freshly eclosed starvation-selected adults are already 80% more starvation resistant than their unselected controls (Chippindale et al. 1996). One then might expect that under fed conditions, starvation-selected populations would have greater reserves to invest towards reproduction. However this is not the case, as starvation-selected populations display low fecundity (Wayne et al. 2006). This may suggest that starvation selection programs flies to resist allocating energy towards reproduction as a cost to improve starvation resistance. This tradeoff is also observed in natural populations of *D. melanogaster* where the amount of

ovarian lipids are positively correlated with fecundity and negatively correlated with starvation resistance (Kalra and Parkash 2014). While the mechanisms that drive this tradeoff are poorly understood, genetic manipulations that alter the accessibility of lipids from the larval fat body during either metamorphosis (*Ilp6*, Bai et al. 2012) or adulthood (*diap1*, Aguila et al. 2013) increase starvation resistance at the expense of fecundity.

Experimental selection for increased longevity leads to a correlated increase in starvation resistance, which may suggest that these traits share a common genetic basis (Rose et al. 1992). Therefore, experimental selection for starvation resistance should lead to a correlated increase in longevity. However the results from starvation-selection experiments are equivocal, with studies finding increases, decreases or no difference in the lifespan of starvation-selected populations (Rose et al. 1992; Harshman et al. 1999; Archer et al. 2003). This paradox was resolved by tracking both traits over the course of a starvation-selection experiment. It was found that while each trait initially improved in response to selection, longevity began to decline in later generations despite continued improvements in starvation resistance (Archer et al. 2003). The concurrent improvements in starvation resistance and longevity in the early generations may have been due to selection on genetic variation associated with generalized stress resistance. However after many generations of selection, loci that independently improve starvation resistance likely accumulated, some of which had a negative impact on longevity (Archer et al. 2003; Rion and Kawecki 2007).

In both natural populations and selection experiments, adaptation to low energy environments shifts genetic variation in energetic homeostasis in favor of storage and retention, which leads to evolutionary costs. In other words, flies can be genetically

predisposed to become obese and genes that favor fat storage can have a negative impact on fitness. Because energy allocation is important to all organisms, some thought starvation-selected *Drosophila* could be used as a model to address some of the basic questions related to obesity in humans. While this will be discussed in greater detail in a later section, the primary focus of this dissertation will be to use starvation-selected *Drosophila* as a model to understand the genes that contribute to obesity and how excess fats promote disease.

1.3 Obesity is a complex condition caused by interactions between many different environmental and heritable factors.

Global rates of human obesity are at an all time high. This is a major health concern because obesity is a leading risk factor for many preventable diseases, which impact the quality and duration of life. While the mechanistic basis of these associations is an area of intense research, studies have shown that increased body mass index (BMI; kg/m^2), is a risk factor for reduced lifespan and strongly associates with cardiovascular disease, type-II diabetes and certain types of cancer (Ng et al. 2014; Segula 2014; Arnold et al. 2016). Obesity is also a common feature of the metabolic syndrome, a multi-factorial clinical state, in which patients are at high risk for cardiovascular disease and type-II diabetes (Grundy 2015). In addition to its implications in human health, treatment of obesity and its associated disorders is expensive which has profound economic consequences. While the medical costs that are directly attributable to obesity may be challenging to assess, a comprehensive review of 33 independent analyses estimated the medical costs of overweight and obesity in the United States to be nearly 114 billion dollars in 2008 alone (Tsai et al. 2011).

Most countries around the world have reported exponential increases in the number of individuals with Body Mass Indices (BMI; kg/m^2) greater than thirty, since 1980 (Stevens et al. 2012; Ng et al. 2014). In 2008, the number of obese individuals worldwide increased to approximately 486-530 million with the total number of overweight (BMI>25) individuals projected to have reached 1.41-1.51 billion (Stevens et al. 2012). Despite these large global patterns, population-level obesity rates range drastically, with rates among age-standardized females as low as 1.4% in Bangladesh to 74.8% in Nauru in 2008

(Stevens et al. 2012). The acceleration of obesity rates also varies by nation. For example, in many developed nations the rates of obesity increase have slowed over the past 10 years, with childhood obesity rates beginning to stabilize in some of these countries as well (Olds et al. 2011; Ng et al. 2014). While it is likely that large-scale trends in global obesity are due to technological advances that promote calorie-rich diets and decreased physical activity (Malik et al. 2012), population-level differences and shifting growth rates in developed nations are largely unexplained. While further understanding of these complex patterns will assist epidemiological efforts moving forward, the total number of affected individuals remains exceptionally high and will only continue to grow as obesity rates are expected to rise in much of the developing world (Ng et al. 2014).

While human health concerns and staggering medical costs have driven research focused on understanding the etiology of obesity and its associated disorders, there is still much that remains unknown. It has become clear that obesity is a complex condition that is shaped by the interactions between many environmental and heritable factors. Fundamentally, obesity is an issue of energy imbalance. Factors that either increase energy acquisition and storage or decrease consumption will drive a positive energy balance and promote fat accumulation. However stored fats do not affect everyone equally. Individuals with similarly high BMIs may completely differ in their risk of developing metabolic disorders (Despres 2012). Complications arising from obesity are more dependent on *where* and *how* fats are stored than the total amount alone. Individual differences in body fat distribution play a critical role in the progression of many diseases with the main distinction made between subcutaneous and intraperitoneal (or visceral) fat stores. Studies suggest that subcutaneous adipose tissue generally provides a benign neutral reserve for

stored fats while visceral adipose tissue is highly associated with cardiometabolic risk (Shimabukuro et al. 2013). Subcutaneous and visceral adipose tissues have a fundamental limit on the amount of fat they can store. When this limit is exceeded, lipids become ectopically stored within the cells of the internal organs (Bastien et al. 2014). High levels of ectopic fat lead to a phenomenon called lipotoxicity, a toxic cellular state that is highly correlated with structural and functional deterioration of the organ (Bastien et al. 2014).

Genetics play an important role in the distribution of these fat depots. This is particularly apparent in individuals with lipodystrophic disorders, where low levels of subcutaneous adipose tissue lead to the accumulation of ectopic fats and severe metabolic disorders (Nelson et al. 2013; Nolis 2014). While lipodystrophic disorders highlight extreme perturbations of lipid homeostasis, a wide-range of genetic variation in human populations likely exists, generating a large distribution of individual susceptibilities.

Differences also exist in the cellular forms and function of adipose tissue itself as various factors may promote a shift in adipocytes favoring energy storage (white adipose tissue) to those capable of utilizing energy to generate heat (brown adipose tissue; Schulz and Tseng 2013). While white and brown adipose tissue mark the extreme cellular subtypes, an array of “beige” adipocytes lay in-between, increasing the potential for cellular variation (Harms and Seale 2013).

It has long been accepted that obesity is highly heritable, ranging from 20-80% across various studies (Maes et al. 1997). Over the past 15 years, a large number of genome-wide association studies have attempted to elucidate the genetic basis of obesity. While the number of identified candidates remains relatively low, we have learned more

about the genetic basis of obesity in the past 10 years than in any point in human history and have come to understand that it is an extremely polygenic condition.

Obesity may also be acquired through non-genetic mechanisms of inheritance, such as epigenetic regulation of the intrauterine environment (Stöger 2008). While epidemiological studies support the idea that maternal nutrition influences the metabolic state of the child, the mechanistic basis of this association is poorly understood (Ravelli et al. 1976). However, a growing body of evidence suggests that parental influences are associated with both changes in chromatin structure through histone modifications and DNA methylation, and deposition of non-coding RNAs (Burgio et al. 2015). Another factor contributing to obesity that has recently gained interest is the effect of the gut microbiome on host metabolism. While the mechanistic basis of these associations are still poorly understood, the relative compositions of gut microbial species have been linked with different cardiometabolic disease states, and are thought to influence chronic inflammation (Aron-Wisnewsky and Clément 2015; Miele et al. 2015).

The current state of obesity may then be driven by global-scale changes in food production and availability, a shift towards sedentary lifestyles, genetic variation influencing the quantity, quality and distribution of stored fats, and epigenetic forces that program the metabolic profile of the fetus *in utero*. This has led to a wide range of theories on the evolutionary origins of obesity which are not necessarily mutually exclusive and likely not exhaustive (Genné-Bacon 2014). Here we will briefly discuss some of the environmental and genetic factors that are thought to shape obesity as well as the current theories on the evolutionary origins of obesity.

Environmental factors including the increased accessibility of calorie dense foods and a shift towards a sedentary lifestyle are important drivers of the current state of obesity.

Food intake and physical activity are two factors that balance energy homeostasis, affecting the rates of energy input and utilization respectively. Over the past several decades technological advancements have shifted the quantity and quality of global food supplies and reduced the amount of physical labor required for many aspects of life (Hill et al. 2003; Hill 2006; Swinburn et al. 2011; Hallal et al. 2012). These factors have created an environment where total energy consumption exceeds utilization, generating a positive energy balance that is believed to be the primary cause of increased obesity around the world (Hill et al. 2003; Crino et al. 2015). Obesity is generally thought of as a chronic condition in which fat stores gradually accumulate over time. Some analyses have found that a net increase in total daily energy as low as 15 kcal is sufficient to drive yearly increases in body weight of ~1.8-2.0 pounds in 20 to 40 year old adults (Hill et al. 2003). Understanding the factors that shape a positive energy balance along with their global distribution will lead to better predictions of obesity rates around the world and offer insight into intervention strategies.

Dietary changes have largely increased the amount of consumed energy in nearly every part of the world (Vandevijvere et al. 2015). In fact, highly processed, calorie dense foods have become so readily available that health issues related to over-nutrition have become more prevalent than under-nutrition on a global scale (Crino et al. 2015). Wholesale shifts in the world's food supply have been driven by technological advancements that have made nearly every aspect of production more efficient from agricultural innovation to improvements in production, shipping and preservation

(Christian and Rashad 2009; Crino et al. 2015). The industrialization of food production has greatly reduced costs and initiated a transition towards the consumption of ultra-processed foods, which have been shown to contain higher levels of total energy due to increased levels of sugar, saturated fat and sodium (Christian and Rashad 2009; Monteiro et al. 2011; Moubarac et al. 2013; Baker and Friel 2014). Problems associated with processed foods are exacerbated by the increased consumption of sugary beverages, particularly carbonated soft drinks which are one of the most important factors driving the increased global consumption of sugar (Nielsen and Popkin 2004; Moubarac et al. 2013; Baker and Friel 2014). Processed foods also typically lack key macronutrients including protein and fiber (Monteiro et al. 2011; Moubarac et al. 2013), which are important factors in weight maintenance and promoting satiation of appetite (Slavin 2005; Hall et al. 2012; Arciero et al. 2013; Tremblay and Bellisle 2015).

The drastic changes in food quality over the latter half of the 20th century coincided with increased overall abundance. This manifested in large food portions which steadily grew in size from 1977 to 1998 (Nielsen 2003). Portion sizes are highly correlated with increased total energy consumption with many studies reporting a 30% or greater increase in consumption when subjects are offered a larger portion size (reviewed in Steenhuis and Vermeer 2009). These factors among others are responsible for promoting an obesogenic environment, which led to large increases in consumed energy as global daily calorie intake was estimated to have increased from 2250 kcal per person in 1961 to 2750 kcal by 2007 (Crino et al. 2015). In roughly the same time period (1970-2000) individual daily energy consumption in the U.S. also increased by roughly 500 kcal, which coincided with an average adult weight increase of ~19 pounds (Swinburn et al. 2009).

Many studies have demonstrated that the estimated increases in food energy availability are more than sufficient to explain observed increases in body weight in most parts of the world (Swinburn et al. 2009; Scarborough et al. 2011; Vandevijvere et al. 2015). These studies, combined with evidence from a comprehensive survey in the United States that found an extremely small impact of physical activity on the incidence of obesity (Dwyer-Lindgren et al. 2013), have led some to suggest that increased food supply is the primary driver of the global obesity crisis (Crino et al. 2015; Vandevijvere et al. 2015). While there is evidence to support this idea, it is important to note that the measurements in these studies are either relatively crude (i.e. individual dietary consumption was estimated from national food supply data, Swinburn et al. 2009) or subject to potential bias due to self-reporting error (i.e. self reported physical activity rates, Dwyer-Lindgren et al. 2013). The combination of these reports and a general lack of data on global physical activity trends in the late 20th century (Hallal et al. 2012) have convoluted the relative impact of physical inactivity on the current prevalence of obesity. However, it is widely accepted that technological advancements since the industrial revolution have changed the amount of physical activity required for labor, transport and leisure (Hallal et al. 2012; Hill et al. 2012). Some have argued that understanding how these advancements have affected total energy expenditure rates is deserving of further analysis (Bauman et al. 2015). While the data are relatively limited, there is evidence to suggest that physical activity levels in developed nations have remained constant or slightly increased over the past 10-30 years (Westerterp and Speakman 2008; Hallal et al. 2012; Dwyer-Lindgren et al. 2013). Despite this, worldwide levels of physical activity were low in 2012, with approximately 31% of adults reported to have engaged in little to no physical activity on a weekly basis (Hallal et

al. 2012). It is therefore possible that activity levels were low prior to changes in nutrition that developed in the 1970's and set the stage for the current epidemic. There is some data to suggest that decreased activity in the workplace began in the mid-20th century as the fraction of low activity jobs in the U.S. workforce increased from 1950-2000 (Brownson et al. 2005). Regardless of the relative impact of diet or activity on the current state of obesity, low levels of physical activity negatively correlate with BMI across multiple countries (Dyck et al. 2015), suggesting that interventions to increase physical activity may be beneficial. Longitudinal studies using objective measures such as accelerometry-based methods will be critical in tracking trends in physical activity moving forward (Dyck et al. 2015).

While nutrition and exercise are some of the most well characterized factors that influence obesity but there is still no scientific consensus on how exactly they have shaped the current epidemic of obesity and related diseases around the world (Swinburn et al. 2011). Because diet and exercise are effective interventions to reduce body weight (Clark 2015), studies have suggested small behavioral changes such as walking for 15 minutes each day or skipping a snack would be sufficient to counter the predicted 15 kcal positive energy balance that drives weight gain for much of the population (Hill et al. 2003). While small lifestyle changes might be effective in slowing the rise of obesity, further measures would be required to generate the negative energy balance required for weight loss. Because one pound of body fat is estimated to contain 3500 kcal of energy (Hall 2008), the U.S. Department of Health and Human Services (DHHS) recommends reducing weekly caloric intake by 500 for every 1 pound of desired weight loss (DHHS, *AIM for a Health Weight*). While this model has been widely accepted and used as a target for weight loss

interventions, the physiological processes of weight loss in practice have been shown to be highly dynamic as the body adapts the expenditure of energy in response to energy deficit over time (Hall 2008; Hall et al. 2011). For instance, increased exercise may lead to compensatory responses that vary among individuals, ranging from changes in metabolism to behavioral adaptations that stimulate appetite, which ultimately balance energetic homeostasis and slow weight loss (King et al. 2007; Blundell et al. 2015). Our understanding of the interactions between the environment and energy homeostasis is likely to increase in complexity as we learn more about additional forces, including metabolic effects associated with the gut microbiota (Payne et al. 2012; Rosenbaum et al. 2015). While these environmental factors may largely explain the current world-wide increase in obesity, individual and population-level differences in the face of similar environments may be shaped by other factors.

The genetic basis of obesity

Studies on the heritability of body mass index (BMI) in twins (Stunkard, Foch, et al. 1986; Stunkard et al. 1990) and in correlation of adoptee BMI to biological or adoptive parent (Stunkard, Sørensen, et al. 1986) have long suggested a genetic component to obesity. These preliminary reports were later corroborated by numerous studies which found high levels of broad sense heritability (h^2) of BMI between parent/offspring or sibling pairs, with heritable factors estimated to explain between 20-80% of the variance in BMI (reviewed in Maes et al. 1997). In studies of monozygotic twins where genetic material is nearly identical, correlation in BMI is even higher ranging between 50-90% (Maes et al. 1997). While this could be due to a shared early environment h^2 values have been reported

to be as high as ~ 0.7 even when monozygotic twins are reared apart (Stunkard et al. 1990). Studies have largely supported the idea that genetics is a more likely predictor of BMI than environmental factors, particularly in young subjects, where additive genetic effects explain a much larger portion of the overall variation in BMI than environmental influences (Silventoinen et al. 2010; van Dongen et al. 2013).

In addition to BMI, genetic factors have been found to explain high levels of variance in many traits associated with the metabolic syndrome, including the fasting levels of important lipid metabolites (total cholesterol, low-density lipoprotein, high-density lipoprotein and triglycerides), components of carbohydrate metabolism (glucose and insulin) and blood pressure (systolic and diastolic pressure; van Dongen et al. 2013). Genetic factors have also been shown to contribute to the overall distribution of body fat, with respect to both the localization (i.e. trunk, lower body; Malis et al. 2005) and tissue subtype (i.e. subcutaneous and visceral adipose tissues; Fox et al. 2007).

Because obesity is highly heritable it is possible that population-level differences in global obesity rates (Stevens et al. 2012) are driven by genetic variation, with some individuals or populations more susceptible to increasing body fat in response to similar environmental changes. Conversely, local environments could be shaped by socio-economic or political climates that alter factors such as the population-level food supply (Swinburn et al. 2011). These hypotheses are difficult to discriminate, largely because the genetic basis of obesity remains largely uncharacterized. However, several lines of evidence suggest that genetics may play a role in shaping the global distribution of obesity rates. Firstly, populations around the world have wide-ranging rates of obesity and in some instances, when populations become admixed, BMI levels positively correlate with the

degree of ancestry, even after controlling for several socioeconomic factors (Stevens et al. 2012; Norden-Krichmar et al. 2014; Goonesekera et al. 2015). This evidence suggests that genetic variation within a given ethnicity may be sufficient to affect phenotypic change in BMI. This idea is further supported by genome-wide association studies, which have found evidence for loci associated with BMI that vary across populations and ethnic cohorts (reviewed in Grarup et al. 2014). This may not be entirely surprising as an extensive amount of genetic variation is separated across geographical space, with polymorphisms from 1,092 individuals across 14 international populations demonstrating large-scale regional differentiation (McVean et al. 2012). Still it remains unclear as to what extent this variation is capable of explaining population-level differences in BMI. To address this some studies have begun to track regional distributions of obesity-associated loci (Dorajoo et al. 2012; Raj et al. 2013). While these studies provide some evidence for population-level differences in several obesity-associated loci, they are measured in only a small number of markers and were insufficient to explain intra-population differences in BMI within the Indian subcontinent (Raj et al. 2013). These types of experiments will continue to improve as more obesity-associated loci are discovered and incorporated into the analysis. Indeed, one recent study which included ~12,000 loci, found that genetic variants could explain a small but significant amount of the variation in BMI across 14 European populations (Robinson et al. 2015). While future studies that incorporate additional loci across more diverse populations will offer further insight, the preliminary data suggest that genetics plays a role in shaping population-level differences in obesity rates.

The clearest evidence for a genetic component to obesity comes in the form of inherited Mendelian disorders. Monogenic forms of obesity are quite rare and associate

with a small number of genes, with nearly 200 known mutations that map to 11 different genes (Mutch and Clément 2006; Rankinen et al. 2006). Many of these genes are associated with regulation of nutrient intake and expenditure through feedback mechanisms in the hypothalamus (Farooqi and O'Rahilly 2005; O'Rahilly and Farooqi 2008). Typically these disorders present with severe early-onset obesity which can be debilitating and may lead to early mortality (Farooqi and O'Rahilly 2005). Identification of genetic disorders with mutations in the leptin gene (*LEP*) led to the development of hormone replacement therapies, which have proven to be effective treatment options (O'Rahilly and Farooqi 2008). On the other end of the spectrum are mutations that lead to lipodystrophic disorders, where adipose tissue depots are either partially or completely depleted, primarily occurring through mutations in one of 12 known genes (Vatier et al. 2013). Interestingly, some of the consequences of severe obesity and lipodystrophy are similar. As adipose tissue is either completely saturated or ablated, fats are ectopically stored in peripheral tissues leading to organ dysfunction and systemic complications such as insulin resistance (Vatier et al. 2013).

While monogenic disorders highlight the extreme genetic contributions to fat storage and utilization, common obesity is largely polygenic, representing a continuous distribution of individual predisposition and susceptibility. In order to understand the genetic basis of obesity, some have begun trying to identify variants in the human genome that are commonly associated with obese phenotypes (Walley et al. 2009). While some initial studies allowed for the simultaneous analysis of several hundred thousand polymorphisms on SNP-array chips (Walley et al. 2009), recent advances have increased that number to ~2.5 million (HumanOmni2.5-8 BeadChip, Illumina Inc, San Diego CA.). SNP

chips are cost efficient and cover many common polymorphisms, but are unable to capture the entirety of human variation. For instance, deep-sequencing of over 1000 individuals found ~38 million SNPs with many more variants in the form of insertions and deletions (McVean et al. 2012). Efforts to identify the genetic basis of obesity from these large number of polymorphisms have been successful in uncovering interesting loci (Willer et al. 2009; Fall and Ingelsson 2014; Locke et al. 2015), but still only account for a small fraction of the overall heritability with studies generally reporting $< \sim 10\%$ of variance in BMI explained by candidate SNPs (Bogardus 2009; Xia and Grant 2013; Locke et al. 2015). With genetic factors estimated to explain ~20-80% of variability in BMI (Maes et al. 1997), a large gap remains in our understanding of the genetic landscape of obesity. This gap may begin to narrow as we gain understanding into the synergistic effects of epistatic interactions between co-inherited alleles, however it is likely that a large number of variants with low effect sizes remain to be implicated in the phenotype. Despite efforts and meta-analyses to increase sampling sizes to discover more associations, GWAS studies are further limited by their inability to consign causality to candidate loci. Even as strong candidates emerge across multiple studies, such as polymorphisms in the fat mass and obesity-associated (*Fto*) gene (Loos and Yeo 2013; Xia and Grant 2013; Tan et al. 2014), they may alter unpredicted targets. In this case, later studies demonstrated the intronic *Fto* SNP affected a cis-regulatory enhancer for the nearby Iroquois-class homeobox (*Irx3/5*) gene. The reported T-to-C transition was found to promote white adipocyte differentiation by altering the binding affinity for the ARID5B transcription factor (Claussnitzer et al. 2015; Herman and Rosen 2015). The inability of GWAS to determine causality is an inherent limitation of the technique and an issue that will become more complex as the

dynamics of transcriptional regulation and nuclear architecture are unraveled, including long range (40-80kB) cis-regulatory and interchromosomal trans-acting enhancers (Zhang et al. 2013; Tai et al. 2014). Despite these limitations GWAS has uncovered a large amount of genetic variation associated with complex traits over the past 10 years and led to discoveries such as *Irx3/5* may have been overlooked without such study. Understanding the limitations and refining methods to determine causality in model organisms may eventually improve the efficacy of GWAS in understanding the genetic variation that contributes to obesity.

The evolutionary origins of obesity

Natural forces may shape the upper and lower thresholds for body fats (Genné-Bacon 2014). Increased fat storage may be adaptive for its utility in surviving periodic famines, importance in reproduction and ability to regulate temperature through insulation (white adipose tissue) or heat generation (brown adipose tissue) (Genné-Bacon 2014). Conversely, too much fat could be maladaptive by reducing locomotion, increasing the risk of predation or maintaining the high energetic cost of constant foraging (Genné-Bacon 2014). Despite the importance of body fat in maintaining energetic homeostasis, there is no clear understanding of how evolution has shaped the quantity and distribution of body fats across species and between individual organisms. This question became increasingly important as the rates of obesity and diabetes spiked over the later half of the 20th century, sparking many theories which are still contested today.

One of the first theories on the evolutionary origins of obesity was the thrifty gene hypothesis, which suggests that the genetic variants that are capable of efficiently storing

and utilizing body fats are selected for during famine events that have occurred over evolutionary time (Neel 1962). The rising rates of obesity and diabetes in westernized civilization would then simply be a consequence of a mismatch between genetic predisposition to retain energy and an overwhelmingly positive energy environment (Neel 1962). By 1989 this hypothesis was partially rebuked by its own author, James Neel, who stated, “The data on which that (rather soft) hypothesis was based have now largely collapsed...” (Neel 1989). In part, this was due to a lack of evidence for positive selection on the low number of genetic candidates that existed at the time (Neel 1989). Relatively recent advancements in the genomic era have allowed for the discovery of more obesity-associated loci and renewed interest in testing the thrifty gene hypothesis. However, GWAS studies over the past decade have found little support for positive selection on any of the risk loci in human populations (Southam et al. 2009; Ayub et al. 2014). Another criticism of the thrifty gene hypothesis is that it has been unable to predict differences in body fat between different populations (Genné-Bacon 2014). Part of this may be due to a lack of knowledge of the evolutionary history of different populations. For example, obesity rates exceed 50% for many island nations in the Pacific Ocean (Stevens et al. 2012). However because the evolutionary history of these populations is not fully understood, they are used as an example for and against the thrifty gene hypothesis, with some suggesting the tropical climates have a low history of famine, while others suggest the opposite (Genné-Bacon 2014; O’Rourke 2014). Others have argued that if famines have driven selection since the beginning of human history, nearly all thrifty alleles would be fixed and most everyone would be obese (Speakman 2008). Furthermore if famines are a more recent phenomenon in human history due to a shift from a hunter-gathering lifestyle to

dependence on agriculture, the number of famines that actually cause significant mortality are likely too rare to affect evolutionary change (Speakman 2008).

Due to some of these concerns, the thrifty gene hypothesis has become controversial and many others have put forth a variety of compelling alternatives (reviewed in Genné-Bacon 2014). For instance, the thrifty epigenome hypothesis suggests that maternal nutrition preconditions the metabolic profile of the developing fetus *in utero* through epigenetic mechanisms (Stöger 2008). This is supported by the study of offspring from mothers who gestated during a famine in Netherlands during World War II (“The Dutch Hungry Winter” study, reviewed in Genné-Bacon 2014). Male offspring were more prone to develop obesity and diabetes, which was later found to be associated with altered DNA methylation patterns of key metabolic genes (Tobi et al. 2009). Some have suggested that epigenetic adaptations to westernized lifestyles may be driving the plateauing obesity rates that are currently being observed in many developed nations (Genné-Bacon 2014). Another theory, the drift gene hypothesis, suggests that human innovations over the past 2 million years have decreased the risk of predation and effectively eliminated the selective pressures that maintain the upper limit of fat storage. These freedoms are thought to have lifted selective constraints, allowing genetic drift and mutation to drive individual susceptibility (Speakman 2008).

These theories are not necessarily mutually exclusive. The dynamic nature of evolution likely incorporates pieces of each to drive the wide variation in body fats found both within and among species observed today. While an understanding of how obesity evolves is an interesting question in its own right, it is also an important matter for human health. For example, the thrifty gene hypothesis predicts that the human genome is better

adapted for ancestral environments. This is the basis behind dietary interventions designed to mimic the foods eaten by our hunter-gatherer ancestors, commonly known as the “Paleo” diet. The Paleo diet has been shown to improve the metabolic health of patients with type-II diabetes (Masharani et al. 2015). Conversely, if epigenetic mechanisms are found to primarily control metabolism, efforts may be focused to improve maternal nutrition while increasing research efforts to understand epigenetic mechanisms. While not the explicit goal of the work described here, predictions from these hypothesis may be rigorously tested with experimental evolution in model organisms.

1.4 *Drosophila* are a well suited model organism to study obesity and its associated diseases.

Obesity is a complex disorder that represents a fundamental imbalance in energetic homeostasis. It is a function of all levels of biological organization, ranging from the ecological factors that shape the availability of resources, to the metabolic cellular process that govern storage and utilization. The wide range of factors that contribute to the etiology of obesity and its associated disorders in humans makes it difficult to study. Due to the deep evolutionary conservation of metabolic processes across metazoans, researchers have turned to model organisms to understand the core environmental and genetic factors that influence metabolism.

Recently *Drosophila melanogaster* has emerged as an important platform of discovery in obesity research as many of the genes and organ systems responsible for maintaining energetic homeostasis are functionally conserved. For instance, both the systems of hormonal regulation and the cellular signaling pathways that maintain carbohydrate metabolism are functionally conserved (Das and Dobens 2015). In some instances, the degree of homology is quite remarkable, with mammalian insulin able to activate the *Drosophila* insulin receptor and vice versa (Sajid et al. 2011). In total it is estimated that ~75% of disease-associated genes in humans share a high degree of sequence homology in *Drosophila*, with ~33% predicted to have functional homology (Bier 2005). Because of this, the *Drosophila* scientific community has developed several important resources, which allow for large-scale screens to identify genes that contribute to metabolic defects (Dietzl et al. 2007; Mackay et al. 2012). *Drosophila* are particularly amenable for the genetic analysis of complex traits because in most cases they exhibit

lower levels of redundancy (Bakal 2011; Zhang 2012) and researchers have developed sophisticated tools that enhance tractability (Duffy 2002; Dietzl et al. 2007; Yu et al. 2013). As discussed earlier in this chapter, *Drosophila* possesses a wide range of natural variation in total lipid content, which may be controlled by genetic factors and is shaped by ecological forces. These complex gene/environment interactions, which make obesity difficult to study in mammals, can be readily dissected by modeling different components of obesity in the laboratory. To date, researchers have modeled obesity in *Drosophila* through dietary modification, genetic manipulation, alteration of the gut microbiome and adaptation to evolutionary stress (Chippindale et al. 1996; Harshman et al. 1999; Birse et al. 2010; Lee et al. 2010; Sujkowski et al. 2012; Buescher et al. 2013; Na et al. 2013; Reynolds 2013; Newell et al. 2014; Diop et al. 2015). The experimental treatment in some of these models induces characteristics that resemble the metabolic syndrome in mammals, including the progression of insulin resistance and heart disease (Birse et al. 2010; Na et al. 2013). There are several important limitations of the *Drosophila* model in obesity research. For instance, *Drosophila* lack brown adipose tissue, which is an important component of thermogenesis in mammals. *Drosophila* also have an open circulatory system, which limits the study of vascular disorders that are commonly associated with obesity. Despite these limitations *Drosophila* have been used to examine the basic physiological and genetic mechanisms that link adiposity to increased cardiometabolic risk. Here we will focus our discussion on the metabolic similarities between *Drosophila* and mammals, as well as highlight recent studies on obesity-associated heart disease.

The fat body plays a central role in maintaining metabolic homeostasis.

One of the primary sites of metabolic regulation in *Drosophila* is the fat body, a heterogeneous tissue which is functionally homologous to mammalian adipose tissue, but is also responsible for immune function and integration of systemic signals (Hoffmann and Reichhart 2002; Arrese and Soulagès 2010; Bai et al. 2012; Rajan and Perrimon 2012). Throughout larval development the fat body serves as a nutritional sensor and adjusts cellular metabolism to couple available energy with growth across various tissues (Mirth and Riddiford 2007). Larval acquisition of resources is vital for holometabolous insects to provide the energy required to support growth and maintenance during metamorphosis and young adult life (Aguila et al. 2007). As larvae approach pupariation a series of pulses of the steroid hormone 20-hydroxyecdysone (20E) trigger the onset of metamorphosis, which results in profound changes in the structure and distribution of the fat body (Thummel 1995; Aguila et al. 2007). Specifically, the larval fat body dissociates from tightly packed clusters into individual cells, which may persist into the first several days of adulthood to provide energy resources for the newly eclosed animal (Hoshizaki 2005; Aguila et al. 2007). The adult fat body is thought to be synthesized *de novo* during metamorphosis, giving rise to a diffuse tissue that is predominantly localized to the abdomen but found distributed throughout the entire animal (Haunerland and Shirk 1995; Hoshizaki 2005).

Within fat body cells, highly dynamic lipid droplets serve as the primary site of lipid storage and breakdown (Kuhnlein 2012). Several protein families associate with lipid droplets, including lipases and perilipins, which are evolutionarily conserved and function under control of similar cellular networks that stimulate lipolysis to mobilize energy in

response to low nutrient levels in mammals (Arrese and Soulages 2010). Genetics play a large role in regulating the size and number of lipid droplets, which are important factors in maintaining healthy levels of stored fat (Krahmer et al. 2013). Variants that alter this balance in mammalian adipocytes ultimately influence the individual capacity for fat storage, which generates a wide distribution of susceptibilities to many diseases (Krahmer et al. 2013). Some of these genes and associated pathologies are conserved in *Drosophila*. For example, missense mutations in the human lipid droplet-associated protein, adipose triglyceride lipase (ATGL), lead to neutral lipid storage disease (NLSD), a rare condition marked by high systemic TG levels in various tissues and increased risk for cardiovascular disease (Schweiger et al. 2009). The *Drosophila* homolog of ATGL, brummer lipase (*bmm*), can be knocked out through the introduction of loss-of-function alleles which similarly lead to increased TG accumulation and heart dysfunction (Grönke et al. 2005; Diop et al. 2015).

The mechanisms that control the coordination of nutritional status and metabolism are also highly conserved in *Drosophila*. Specialized neurosecretory cells in the brain, including the insulin producing cells (IPCs) and corpora cardiaca (CC), secrete insulin-like peptides (Ilps) and adipokinetic hormone (Akh) respectively, which affect metabolism in peripheral tissues analogously to the pancreatic release of insulin and glucagon in mammals (Arrese and Soulages 2010; Das and Dobens 2015). These molecules activate downstream signaling cascades in the fat body which are highly interconnected, forming a network that shifts between cellular programs that promote either anabolic energy storage in response to Ilp signals or catabolic energy mobilization in response to Akh (Arrese and Soulages 2010; Das and Dobens 2015).

Drosophila have 8 insulin-like peptides (Ilp1-8) which share a degree of functional redundancy, but are differentially expressed in a tissue specific manner (for a full review see Kannan and Fridell 2013). The primary function of the Ilps is to couple cellular metabolism with nutritional status. For instance, Ilp2 and Ilp3 may be secreted from the IPCs in response to high circulating levels of amino acids or sugars respectively (Kim and Neufeld 2015). These neuropeptide hormones bind the *Drosophila* insulin-like receptor (*InR*) in peripheral tissues, which initiates a cascade that activates several conserved members of the core insulin signaling pathway, including Akt and TOR, which promote anabolic gene expression and cell growth (Das and Dobens 2015). In mammals adipose tissue plays an important role in secreting cytokines in response to nutrient levels to balance systemic metabolism (Leal and Mafra 2013). The *Drosophila* fat body is similarly capable of recognizing dietary macronutrients and releasing cytokines, such as Unpaired 2 (Upd2), which activates systemic Ilp release from the IPCs (Géminard et al. 2009; Rajan and Perrimon 2012). Under starved conditions the fat body expresses and hormonally secretes Ilp6, which acts to negatively feedback on Ilp2 expression in the IPCs (Bai et al. 2012) and promote lipid mobilization through hepatic-like cells called oenocytes (Chatterjee et al. 2014). Ilp6 is also expressed in the fat body during metamorphosis in response to 20E and is required to promote growth of the developing tissues (Slaidina et al. 2009).

Akh largely antagonizes Ilp signaling in *Drosophila* by promoting the mobilization of stored lipids and carbohydrates in the fat body under starved conditions (Das and Dobens 2015). Akh signaling in the fat body is activated through binding of the neuropeptide to the adipokinetic hormone receptor (AkhR), which initiates a G-protein associated signaling cascade leading to the activation of central catabolic regulators such as Protein Kinase A

(Pka) (Grönke et al. 2007). Pka promotes lipolytic signals directly by activating lipid droplet protein (Lsd-1) and further promotes the expression of catabolic genes through activation of Creb and foxo transcription factors (Patel et al. 2005; Arrese et al. 2008; Wang et al. 2011; Yang et al. 2013). Cross-talk and feedback mechanisms between components of the Akh and Ilp signaling pathways allow the cell to adjust to acute nutritional changes.

The functional conservation of the Drosophila heart is remarkable given its largely simplified design.

The *Drosophila* heart is a simple tube, comprised of two rows of semicircular shaped cardiomyocytes which interlock to form a contiguous lumen (Lehmacher et al. 2012). Adherens junctions on the dorsal and ventral aspects of the cardiomyocytes anchor actin myofibrils which run circumferentially through the cells to generate a contractile ring (Lehmacher et al. 2012). The heart tube is localized within the abdomen, closely associated with the dorsal cuticle and contracts in response to both myogenic pacemakers and neurogenic signals (Dulcis 2005). Hemolymph, the primary circulating fluid in arthropods, flows into the heart lumen during diastole through small cellular invaginations formed from neighboring cardiomyocytes called ostia, whose valvular lips passively constrict to block inflow during systole. Another set of specialized cardiomyocytes called intracardiac valve cells break the heart into four primary chambers. The most rostral chamber near the anterior abdomen widens, forming the conical chamber, whose increased size provides the extra force required to eject fluids through the non-contractile thoracic aorta. In *Drosophila* contraction patterns are dynamic as the fly may switch between anterograde or retrograde heartbeats to circulate hemolymph through an open circulatory system (Wasserthal 2007;

Slama 2010). Anterograde contractions are more common and necessary to expel hemolymph through the aorta where it is spilled into the posterior head. The primary pacemaker cell is thought to reside in the caudal chamber of the heart, although others have suggested another pacemaker exists near the conical chamber (Wasserthal 2007; Slama 2010). Relaxation of the heart during diastole is assisted by sets of alary muscles whose myofibrils run perpendicular to those of the cardiomyocytes and tether the heart to the dorsal cuticle at several intervals along the abdomen (Klowden 2007; Lehmacher et al. 2012). The alary muscles are not directly bound to the cardiomyocytes, instead they are bridged by extracellular matrix fibers which are hypothesized to increase the elasticity of the connection (Lehmacher et al. 2012). Several long syncytial muscles run ventrally down the length of the tube. The function of these ventral longitudinal fibers remains unclear, however they are thought to be important in support and may assist in contraction (Lehmacher et al. 2012). Several pairs of rounded pericardial cells border the edges the heart and serve as nephrocytes, filtering the hemolymph as it circulates (Weavers et al. 2009).

While the *Drosophila* and mammalian heart have many obvious differences, early studies identified the genes and signaling cascades that drive differentiation and morphogenesis throughout development to be highly conserved, sparking interest in using *Drosophila* as a model to study congenital heart disease (Bodmer 1995; Bier and Bodmer 2004). The subsequent identification of conserved genes associated with other cardiovascular diseases including muscle defects, conduction blocks and hypertension led to expanded efforts to identify novel genetic factors through large-scale screens and to perform genetic manipulations to study the underlying physiological changes (Piazza and

Wessells 2011; Wolf and Rockman 2011). Some studies have generated models of human cardiac disease in *Drosophila*, which has highlighted the remarkable degree of functional conservation (Sujkowski and Wessells 2015). For example, researchers have developed a fly model for long QT syndrome (LQTS), a genetic disorder caused by mutations in a K⁺ ion channel subunit (*KCNQ1*). Mutations in *KCNQ1* lead to slow cardiac repolarization, which ultimately induces arrhythmia and increased susceptibility to sudden heart failure (Ocorr et al. 2007). Heart dysfunction in flies with mutated *KCNQ* was shown to mirror LQTS, with early onset of arrhythmia and pacing-induced heart dysfunction (Ocorr et al. 2007).

Another group developed a model to study cardiac disorders associated with Duchenne and Becker Musclar Dystrophies, which are genetic diseases marked by mutations in the *dystrophin* (*Dys*) gene which may manifest in dilated cardiomyopathy, arrhythmia and heart failure (Taghli-Lamalle et al. 2008; Taghli-Lamalle et al. 2014). The dystrophin protein plays important roles in transducing both mechanical force and cellular signals (Taghli-Lamalle et al. 2008). *Drosophila dys* mutants have myofibril disorganization, dilated cardiomyopathy and altered contraction patterns, which could be improved by expressing constructs of human *Dys* in the *Drosophila* heart (Taghli-Lamalle et al. 2008; Taghli-Lamalle et al. 2014). The high levels of genetic similarity observed in these disease models has prompted researchers to study gene by environment interactions on cardiac physiology for many factors including exercise, ageing and nutrition (Piazza and Wessells 2011; Diop and Bodmer 2015; Sujkowski and Wessells 2015). The studies focused on the interaction between diet and genes involved in energy homeostasis have provided insight into obesity-associated heart disease.

Lipotoxicity is a common mechanism linking obesity to the development of heart disease in Drosophila.

There are many ways in which obesity may alter cardiovascular health, which vary by individual genetic makeup and environmental factors. In general, obesity may lead to hypertension, increased levels of circulating carbohydrate and lipid molecules, generalized inflammation and atherosclerosis (Hall et al. 2014). Under chronic conditions these factors commonly lead to increased left-ventricular mass, resulting in dilation and low fractional shortening (Alpert et al. 1995). These changes in the left ventricle are associated with hypertrophic remodeling of the cardiomyocytes, fibrosis and increased epicardial and myocardial fat deposits (Poirier 2006; Cavalera et al. 2014; Murdolo et al. 2014). The infiltration of fibrotic and epicardial fat cells within the myocardium may further lead to conduction defects, which contribute to arrhythmic contraction patterns (Poirier 2006; Cavalera et al. 2014). Poor left ventricle function and arrhythmia are highly associated with heart failure and pose a major health risk for obese individuals (Eckel 1997; Mathew et al. 2008; Lavie et al. 2013).

The relative distribution of body fats is a major predictor for cardiometabolic risk factors, as hypertension, inflammation and high circulating metabolites are more highly associated with individual levels of visceral adipose tissue (VAT) than subcutaneous adipose tissue (SAT) or overall body fat (Després et al. 1990; Tchernof and Despres 2013). SAT is hypothesized to be a neutral reservoir, which can store excess fats with relatively low risk for the development of cardiometabolic disease (Despres 2012; Bastien et al. 2014). When lipid levels exceed the storage capacity of SAT, fats are improperly stored in VAT or ectopically in peripheral tissues like the heart or pancreas (Unger et al. 2010;

Bastien et al. 2014). The ectopic accumulation of fats within the myocardium disrupts cellular function, leading to a phenomenon known as lipotoxicity. Lipotoxicity is highly associated with heart failure and thought to be a central mechanism of many obesity-associated disorders (Zhang and Ren 2011; Bastien et al. 2014).

The molecular basis of lipotoxicity is poorly characterized, but may be associated with changes in the availability of substrates used to generate cellular energy. The heart primarily derives cellular energy through the metabolism of glucose and fatty acids (Taegtmeyer 1994). While metabolism of both molecules produce acetyl-CoA for entry into the TCA-cycle, the breakdown of glucose additionally supplies oxaloacetate through pyruvate carboxylation, which is a critical component of the TCA-cycle (Taegtmeyer 1994). Obesity induces high circulating levels of both glucose and free fatty acids. However, obesity also induces the onset of insulin resistance, which reduces the heart's ability to fully utilize glucose (Zhang and Ren 2011). Ultimately this results in a heavy reliance on fatty acids, which reduces the efficiency of ATP production and impacts contraction (Lopaschuk et al. 2007). This likely occurs through the buildup of fatty acid intermediates as the metabolic capacity of β -oxidation is overwhelmed (Zhang and Ren 2011). This stress is thought to both damage myocardial mitochondria and lead to changes in gene expression that may increase inflammation and TG accumulation (Guzzardi and Iozzo 2011).

Researchers have developed different models in *Drosophila* to study lipotoxicity on different levels- to both understand how genetic variation may influence the fundamental storage capacity of adipose tissue, and how the problem is exacerbated by chronic over-nutrition (Birse et al. 2010; Lee et al. 2010; Lim et al. 2011; Palanker Musselman et al. 2011; Sujkowski et al. 2012; Na et al. 2013; Diop et al. 2015). When *Drosophila* are reared

on lipogenic diets which are high in fat or sugar, they develop an obese phenotype, resulting in a higher percentage of body fat, insulin resistance and heart anomalies (Birse et al. 2010; Palanker Musselman et al. 2011; Na et al. 2013: 2). Specifically, chronic over-nutrition disrupts *Ilp* expression in the IPCs, which leads to high levels of circulating sugars, and decreased levels of insulin signaling in peripheral tissues (Birse et al. 2010; Na et al. 2013). This promotes a lipotoxic state, leading to increased cardiac steatosis, associated with conduction defects, arrhythmia and poor contractility due to myofibrillar disorganization (Birse et al. 2010; Na et al. 2013).

Many of the pathophysiological effects of a high calorie diet were found to be the result of hyperactive Tor signaling. Tor was found to respond to a HFD by promoting the expression of genes involved in lipid synthesis such as fatty acid synthase (*FAS*), while repressing the expression of lipocatabolic genes like brummer lipase (*bmm*) (Birse et al. 2010). The deleterious effects of a HFD could be reduced by knocking down many of these components in the Tor pathway specifically in the fat body (Birse et al. 2010). Furthermore, heart-specific knockdown of Tor signaling components reduced cardiac steatosis, which led to improved heart function despite high levels of total body fat (Birse et al. 2010). These findings suggest that obesity-associated heart dysfunction in *Drosophila* is not the result of high body fat *per se*, but a function of cardiac lipid accumulation (Birse et al. 2010).

In the fat body, Tor integrates inputs from changes in nutrition, energy and stress and responds by controlling transcription factors that promote anabolic metabolism and cellular growth. Studies in *Drosophila* have uncovered genetic interactions involved in this signaling pathway, which may contribute new avenues for treatment and explain individual genetic susceptibilities (Lee et al. 2010; Lim et al. 2011; Diop et al. 2015). For example, Tor

hyperactivity leads to increases in reactive oxygen species which are correlated with the increased expression of a stress-responsive gene known as *sestrin* (Lee et al. 2010). Sestrin was found to be an important suppressor of Tor activity, which could reduce body fat and heart disease in hyperactive Tor mutants of *Drosophila* (Lee et al. 2010). Others have studied downstream components of Tor signaling, including sterol regulatory element binding protein (SREBP), PPAR γ coactivator-1 (PGC-1), FAS and Bmm. All of these downstream components were found to be important for body fat accumulation, lipotoxicity and heart dysfunction under a HFD (Birsen et al. 2010; Teleman 2010; Lim et al. 2011; Diop et al. 2015).

There are also genes which may promote lipotoxic heart dysfunction independently of a high calorie diet and not directly related with Tor signaling. This was observed in *Drosophila* that were heterozygous for a loss-of-function mutation in the fatty acid transport protein (*Fatp*). *Fatp* mutants develop high levels of body fat on a standard diet (Sujkowski et al. 2012). This results in the accumulation of cardiac TGs and poor heart function as measured by low stress resistance to external pacing (Sujkowski et al. 2012).

Genome-wide studies of obesity in Drosophila

Due to the conservation of individual genes and gene networks in regulating metabolism in *Drosophila*, some have performed large-scale genomic screens to find genes involved in metabolism in an unbiased approach. While genome-wide studies of obesity are limited in *Drosophila*, they hold promise in identifying many more genes, which can be further studied and functionally validated. One large-scale screen used genome-wide RNA interference to identify ~500 genes which significantly altered TG storage (Pospisilik et al.

2010). These genes were subsequently knocked down in individual tissues including the fat body, where genes involved in hedgehog signaling were identified as important in suppressing TG accumulation (Pospisilik et al. 2010). The study found these genes had conserved function in mice and were responsible for repression of white adipocyte differentiation (Pospisilik et al. 2010). A similar study performed an RNAi screen of 6796 genes in the gut and fat body of adult flies and found 77 genes that positively or negatively affected lipid storage (Baumbach et al. 2014). Of these 77, 58 were previously unidentified as lipid modifiers and 46 had a directly known human homolog (Baumbach et al. 2014). The group followed up on a set of genes associated with Ca^{2+} signaling and found they were capable of inducing obesity, with one gene, Stromal interaction molecule (*Stim*) involved in controlling food intake (Baumbach et al. 2014).

While not explicitly targeting obesity, other studies have utilized the *Drosophila* Genetic Resource Panel (DGRP), a set of fully sequenced inbred lines, to identify polymorphisms associated with macromolecule storage in response to low or high glucose diet (Unckless et al. 2015) and starvation resistance (Mackay et al. 2012). These studies identified a large amount of genetic variation underlying these metabolic traits and found that the most significant loci for any given trait were found in introns or predicted to code for a non-synonymous substitution (Unckless et al. 2015).

1.5 Starvation selected *Drosophila* as a model to study the physiology, genetics and evolutionary origins of obesity.

The focus of this dissertation will be the analysis of populations of *D. melanogaster* laboratory selected for starvation resistance. The populations of study here were established in 2006 by Allen Gibbs, who was interested in investigating the mechanisms of adaptation to starvation resistance, as well as developing a model to study the *genetic* basis of obesity and its associated diseases. To date, the starvation-selected populations have been selected for over 100 generations. In response they have become obese, storing nearly two times the levels of stored fats as their unselected controls. Previous studies have measured many correlated tradeoffs in these lines, some of which resemble characteristics of the metabolic syndrome in mammals. Here, we investigate the physiological consequences of starvation-selection on heart function, the genetic basis of adaptation and how selection affects gene expression during critical developmental windows.

Evolutionary history of the starvation-selected populations

The starvation-selected populations were derived from a previous experimental evolution experiment selecting for desiccation resistance (described in Gefen et al. 2006). The founding population for the desiccation selection experiment was comprised of ~400 adult female *D. melanogaster* collected from the wild in Terhune New Jersey in 1999. After about a year of acclimation to laboratory conditions, the original population was split into 3 large cohorts, each with 3 replicate populations for a total of 9 populations. Every generation each cohort was subjected to one of three environmental conditions. The desiccation selected cohort (populations D_{A-C}) were housed in plexi-glass cages containing approximately 200 grams of silica gel desiccant to remove the environmental water supply.

Because desiccation also requires the removal of food, the D populations were co-selected for starvation resistance. To control for the effects of starvation in the D populations another cohort of 3 populations, the starved controls (populations SC_{A-C}) were given agar plates, which provided a water supply while offering no nutritional value. A third cohort of 3 populations, the fed controls (populations FC_{A-C}) were essentially unstressed, given *ad libitum* access to food and water. All populations were handled in parallel with the exception of the selective treatment, silica desiccant (D_{A-C}), non-nutritious agar (SC_{A-C}) or standard cornmeal medium (FC_{A-C}), during the selection phase of each generation. Selection began each generation after the flies had reached 4 days of adulthood and persisted until 80-85% mortality was reached in the D populations. At this point survivors for all nine populations were fed fresh cornmeal medium and eggs were collected to propagate the next generation.

In 2006, after generation 70 of the desiccation selection experiment, subpopulations were derived from the starved controls (SC_{A-C}) and the fed controls (FC_{A-C}) to begin the starvation selection experiment studied here. The starvation selection experiment consists of 2 major cohorts, the starvation-selected populations (hereafter “S_{A-C}”), which were derived from SC_{A-C} and the fed controls (hereafter “F_{A-C}”), derived from FC_{A-C}. Each generation, ~10,000 four-day-old adult flies for each S population were housed in an individual plexi-glass cage and given non-nutritious agar plates until 80-90% mortality was achieved. For each of the F populations, ~2,000 four day old adult flies were maintained in parallel and given *ad libitum* access to standard cornmeal medium. After the selection phase of each generation, all 6 populations (S_{A-C} and F_{A-C}) were given fresh cornmeal medium, given 4 days to recover, then eggs were collected to propagate the next

generation. To date, the S populations have been selected for 100 generations, however the experiments here were performed roughly between generations 50-80.

Evolved physiologies and correlated responses to starvation-selection

The S populations evolved many physiologies that were similar to previous starvation-selection experiments (Chippindale et al. 1996; Harshman et al. 1999). For instance after ~45 generations, the S flies could survive starvation ~2-3 times longer than the F controls (Reynolds 2013). This was due to large changes in body fat composition as the average S fly carried ~170 μg of total lipids compared to ~70 μg for the average F fly (Reynolds 2013). These changes in lipid content were not associated with changes in other macromolecules, as glycogen and protein levels were not significantly different between F and S flies (Reynolds 2013). The shift towards lipid storage and starvation resistance created a marked tradeoff in fecundity as the S populations had lower daily fecundity than the Fs throughout the first few weeks of adulthood (Reynolds 2013). Unlike previous studies, the S flies were found to have a lower metabolic rate even after accounting for the excess lipid weight as CO_2 production per hour standardized to lean mass was ~40% lower than the F controls (Reynolds 2013). There was also a trend towards lower activity levels in the S populations, however the data failed to reach significance (Reynolds 2013).

The S populations have also evolved a ~24 hour delay in development (Reynolds 2013). This delay increases the S larval feeding period, during which they acquire excess resources, which results in higher lipid content than the F populations upon eclosion (Reynolds 2013). The delay in development is thought to be due to dysregulation of 20E signaling as the S populations have a ~24 hour delay in expression of 20E target genes

(Reynolds 2013). However it is not clear whether this delay in expression is due to a delay in the neural synthesis and release of 20E or a delay in the cellular response of peripheral tissues to 20E. Feeding 20E to F and S larva at the beginning of 3rd instar only partially decreases the developmental delay in the S populations (Reynolds 2013). This could indicate that the S populations have adapted mechanisms to attenuate 20E-induced expression. This is supported by preliminary data which suggest the S larval fat body is less responsive to 20E, as it fails to completely dissociate during metamorphosis and delays programmed cell death in the adult fly (N.D. Bond, personal communication). More experiments are needed to discriminate between these possibilities.

Another set of experiments demonstrated that S flies may have reduced energy expenditure through adaptations that increase sleep duration and impair flight performance (Brewer 2013; Masek et al. 2014). In addition, these studies found evidence to suggest that behavioral adaptations may reduce foraging in response to selection. For instance, acute starvation in wild-type *Drosophila* will suppress sleep, likely in a behavioral response to find food (Masek et al. 2014). However, the S populations maintain a high constant level of sleep throughout starvation. Furthermore, S adults were found to eat less than the F controls and failed to increase compensatory feeding after starvation (Masek et al. 2014).

Summary

Experimental evolution affords the opportunity to understand the physiological and genetic basis of adaptation. Adaptation to laboratory selection for starvation resistance in *D. melanogaster* leads to metabolic disorder and increased total lipid stores, which are at

the heart of the global obesity crisis. The complex factors that contribute to obesity in humans can be simplified and modeled in *Drosophila*. Here we investigate the physiological and genetic basis of adaptation in starvation-selected *D. melanogaster*. In Chapter 2 we study the physiological consequence of starvation selection on the heart, investigating whether heart function is an evolutionary tradeoff with starvation resistance. We report that the S heart is dilated and less contractile than the F controls. Strikingly, the basis of dysfunction is correlated with enlarged fat body tissue, which severely alters the anatomical placement of the heart. We did not observe cardiac steatosis as observed in other *Drosophila* models. Instead excess lipids were found in large lipid droplets within the S fat body, suggesting that selection greatly increases the capacity to store neutral fats. In Chapter 3 we perform an E&R experiment to understand the genetic basis of adaptation. We find that starvation selection had profound effects on allele frequencies, with many large-scale regions across the genome approaching fixation. Allelic frequencies were variable across S populations, which correlated with differences in starvation resistance. To find alleles that responded to selection we generated a novel algorithm to filter the effects of genetic drift. We found ~120,000 loci whose difference in frequency was consistent with selection. These loci mapped to many genes involved in metabolic homeostasis including many in the insulin and adipokinetic hormone signaling pathways. In Chapter 4 I discuss my role in a larger effort to understand the mechanistic basis of delayed larval development in the S populations. Specifically we focused on how gene expression in the fat body differed between selection treatments in response to the late larval 20E pulse. I identified genes that were differentially regulated in response to selection which will provide the basis for future work.

³Department of Medicine, Robert M. Berne Cardiovascular Research Center, University of Virginia School of Medicine, Charlottesville, VA.

⁴School of Medicine- Cardiology, Duke University, Durham, NC.

Author Contributions: C.M.H. and A.G.G. planned experiments with assistance from R.T.B. C.M.H. and A.G.G. performed statistical analyses and wrote the paper. C.M.H and R.T.B. performed semi-automated heart beat analysis (SOHA) and heart structure staining with assistance from R.B. Optical coherence tomography (OCT) was performed by M.J.W. and

histology performed by L.Y. All other experiments were performed by C.M.H. Each author contributed to editing the final manuscript.

2.1 Abstract

There is a clear link between obesity and cardiovascular disease, but the complexity of this interaction in mammals makes it difficult to study. Among the animal models used to investigate obesity-associated diseases, *Drosophila melanogaster* has emerged as an important platform of discovery. In the laboratory, *Drosophila* can be made obese through lipogenic diets, genetic manipulations and adaptation to evolutionary stress. While dietary and genetic changes that cause obesity in flies have been demonstrated to induce heart dysfunction, there have been no reports investigating how obesity affects the heart in laboratory-evolved populations. Here, we studied replicated populations of *Drosophila* that had been selected for starvation resistance for over 65 generations. These populations evolved characteristics that closely resemble hallmarks of metabolic syndrome in mammals. We demonstrate that starvation-selected *Drosophila* have dilated hearts with impaired contractility. This phenotype appears to be correlated with large fat deposits along the dorsal cuticle, which alter the anatomical position of the heart. We demonstrate a strong relationship between fat storage and heart dysfunction, as dilation and reduced contractility can be rescued through prolonged fasting. Unlike other *Drosophila* obesity models, the starvation-selected lines do not exhibit excessive intracellular lipid deposition within the myocardium and rather store excess triglycerides in large lipid droplets within the fat body. Our findings provide a new model to investigate obesity-associated heart dysfunction.

2.2 Introduction

Obesity is a leading risk factor for many diseases, including type-II diabetes, cardiovascular disease and certain types of cancer (De Pergola and Silvestris 2013; Bastien et al. 2014). With worldwide obesity rates at an all-time high, attention has focused on understanding the etiology of obesity-associated diseases. Recently, *Drosophila melanogaster* has emerged as an excellent model to investigate the genetic causes and physiological consequences of obesity. In the laboratory, *Drosophila* can be made obese through dietary changes, genetic manipulation and adaptation to evolutionary stress (Chippindale et al. 1996; Harshman et al. 1999; Birse et al. 2010; Lee et al. 2010; Birse and Bodmer 2011; Lim et al. 2011; Diop and Bodmer 2012; Na et al. 2013; Diop et al. 2015). These models recapitulate many aspects of obesity, and some have provided the tools to investigate how increased lipids affect the heart. For instance, *Drosophila* fed lipogenic diets high in fat or sugar, store higher levels of triglycerides (TG) and exhibit a range of associated cardiomyopathies (Birse et al. 2010; Na et al. 2013). Genetic mutations that alter lipid homeostasis can also induce heart dysfunction. For example, hyperactivation of TOR signaling through reduction of sestrin function or mutation of downstream components of TOR, such as PGC-1 and ATGL lipase, lead to increased total TG and heart dysfunction-including arrhythmia, reduced cardiac contractility and defects in structural integrity (Lee et al. 2010; Diop et al. 2015). Additionally, genetic dysregulation of phospholipid metabolism results in increased expression of *Drosophila* sterol regulatory element-binding protein (*dSREBP*), leading to higher levels of stored fat and alterations to the structure and function of the heart (Lim et al. 2011). Another study found that the loss of

one copy of the gene coding for the *Drosophila* fatty acid transport protein (*dFatp*) results in obese flies, which exhibit low cardiac stress resistance (Sujkowski et al. 2012).

Common among many of these models is the increase in intracellular accumulation of lipids within the myocardium, hypothesized to cause structural and functional damage to the heart (Birse et al. 2010; Lim et al. 2011; Sujkowski et al. 2012; Na et al. 2013; Diop et al. 2015). This lipotoxic effect is well documented in mammals and occurs when TG levels surpass the storage capacity for lipids within adipose tissue (Bastien et al. 2014). In *Drosophila*, the functional equivalent of adipose tissue is the fat body, a heterogeneous tissue responsible for nutrient storage and utilization amidst many other functions (Arrese and Soulages 2010). Within the fat body, highly conserved intracellular lipid droplets act as the primary site of TG synthesis, storage and breakdown (Kuhnlein 2012). In lipotoxic conditions, lipid droplets within the adipose tissue become oversaturated which leads to ectopic fat deposition in non-adipose tissues. In mammals, excess accumulation of lipids in non-adipose tissues is strongly correlated with organ degeneration, leading to disrupted structure and function (Unger et al. 2010). In *Drosophila* this may result in reduced lifespan (Na et al. 2013), altered carbohydrate homeostasis (Birse et al. 2010; Na et al. 2013) and heart dysfunction (Birse et al. 2010; Lim et al. 2011; Sujkowski et al. 2012; Na et al. 2013; Diop et al. 2015).

While obesity has many pathophysiological effects, the ability to store excess lipids may have an ecological advantage in the context of starvation resistance. In nature, lipids stored within the fat body may be used as a vital resource to survive periods of low nutrient availability (Parkash et al. 2012; Aggarwal 2014). Indeed, natural variation for starvation-resistance in *Drosophila simulans* positively correlates with stored fats (Ballard

et al. 2008). In the laboratory, selection for starvation-resistance in *Drosophila melanogaster* leads to correlated increases in stored lipids (Chippindale et al. 1996; Harshman et al. 1999). However adaptation to starvation-resistance incurs evolutionary costs, including reductions in metabolic rate, locomotion and longevity (Rion and Kawecki 2007). While these phenotypes are similar to the increased lipids, impaired activity levels (via geotaxic response) and decreased longevity reported in other obesity models (Birse et al. 2010; Na et al. 2013), to our knowledge there have been no investigations into the physiological consequences of starvation selection on the heart.

We selected replicated populations of *Drosophila melanogaster* for starvation resistance for over 65 generations. In response to selection, the Starvation-selected (hereafter “S”) populations evolved an obese condition, storing nearly twice the level of total lipids as compared to their ostensibly unselected Fed controls (hereafter “F” populations) (Reynolds 2013). The stored lipids are metabolized upon exposure to starvation, and utilized by the S populations to survive nearly 14 days without food. The excess lipids in the S lines accumulate during an extended larval feeding period (Reynolds 2013). However S flies remain obese in adulthood despite consuming fewer calories than their unselected controls when fed *ad libitum* (Masek et al. 2014). There are many evolutionary tradeoffs associated with increased adiposity in the S lines including decreases in developmental rate, fecundity, metabolic rate, activity levels, flight performance and disrupted sleeping patterns (Brewer 2013; Reynolds 2013; Masek et al. 2014). Because many of these phenotypes are suggestive of metabolic disorder, we questioned whether starvation-selected *Drosophila* also exhibited heart dysfunction.

Here, we demonstrate using multiple approaches that starvation-selected *Drosophila melanogaster* have dilated, less-contraction hearts than their unselected controls. Our data and observations suggest that this dysfunction is in part related to expanded fat body tissue which physically interferes with the anatomical position of the heart. We also demonstrate that heart dysfunction in the S populations is associated with increased fat storage, as cardiac enlargement and contractile impairment can be rescued through prolonged fasting. Unlike most obesity models in *Drosophila*, our data suggest S flies do not ectopically store lipids within the myocardium. Instead S flies have adapted by increasing the storage capacity of lipids within the fat body by increasing lipid droplet volume. These findings shed light into the evolutionary origins of obesity and provide a unique model to study the genetics and physiology of obesity associated cardiac disease.

2.3 Methods

Laboratory natural selection for starvation resistance

The starvation-selected (“S”) populations were derived from wild caught *D. melanogaster* collected in Terhune New Jersey in 1998 as previously described (Gefen and Gibbs 2009). In 2007, subpopulations were derived from these lines and subjected to selection for starvation resistance. Each generation, 4 day-old post-eclosion adults were given non-caloric agar and maintained until 80-90% had died. The survivors were fed and used as founders for the next generation. Fed control (“F”) populations were given unrestricted access to food but otherwise handled in parallel with the starvation-selected lines. Each cohort (starvation-selected and fed control) is composed of 3 independent replicates. Experiments conducted here were from generations 65-80. For all experiments the S populations were removed from selection for one generation, maintained and treated in parallel to the controls to remove potential parental effects. All experiments were performed on females.

Semi-automated Optical Heartbeat Analysis (SOHA)

To analyze cardiac contractions we used previously described video microscopy techniques (Karen Ocorr et al. 2007; K. Ocorr et al. 2007a; Fink et al. 2009). For this method it is necessary to surgically expose the fly’s heart in order to make it accessible for high-resolution filming (Vogler and Ocorr 2009). In brief, dissections to expose the fly’s heart within the abdomen were kept in oxygenated saline and high-speed digital movies were taken and analyzed using custom software (sohasoftware.com) for end-diastolic (EDD), end-systolic (ESD) diameter, heart period intervals and arrhythmia (Karen Ocorr et

al. 2007; K. Ocorr et al. 2007a; K. Ocorr et al. 2007b; Fink et al. 2009). Fractional shortening (FS) was calculated as $[\text{EDD}-\text{ESD}]/\text{EDD} \times 100$.

Optical Coherence Tomography (OCT)

Cardiac function was also measured using a custom built OCT microscopy system (Bioptigen, Inc. Durham, NC) as previously described (Wolf et al. 2006; Yu et al. 2013). Flies were briefly anesthetized using CO₂, immobilized, and allowed to awaken prior to performing OCT. M-mode images, resulting from a method that measures heart wall movement during the cardiac cycle were acquired, processed, and analyzed to calculate EDD and ESD, determined from 3 consecutive heart beats. Heart rates were calculated from m-mode images and expressed as the period in seconds per heart beat.

Rescue Experiments

We performed two sets of experiments to reduce TG content in S flies in an attempt to rescue heart function. For adult rescue experiments, both F and S flies were aged 4-5 days then placed on media containing either non-caloric 1% agar or standard cornmeal. S lines were evenly split between these two conditions while F flies were transferred only to fresh standard cornmeal medium, with care taken to maintain similar densities between S and F cohorts. Flies on all treatments were aged for 7 days then subjected to TG measurements, SOHA or OCT.

The larval rescue protocol has been previously described (Masek et al. 2014). In short, F and S larvae were reared in parallel. When F larvae began to wander, 3rd instar S larvae were picked from their media and placed in either fresh standard cornmeal medium

or 1% agar. Eclosing flies were placed on standard cornmeal medium and aged 4-5 days then subjected to TG measurements and SOHA.

Triglyceride and Protein Measurements

Individual flies were homogenized using a motorized pestle in 120 μ L of western lysis buffer (previously described, (Aguila et al. 2013)) on ice. Homogenates were incubated at 70°C for 5 minutes to heat-kill lipases. Samples were centrifuged and the supernatant was used to measure either total TG or total protein levels. For TG, a 1:10 dilution of supernatant to Infinity™ Triglycerides Reagent (Thermo Scientific, Middletown, CA.) was mixed in a 96-well plate. The plate was covered with parafilm to prevent evaporation and incubated for 30 minutes at 37°C, then was measured using a μ Quant™ Microplate Spectrophotometer (BioTek® Instruments Inc., Winooski, VT.) at 540nm. For total protein, a 1:5 solution of supernatant to dye (dye: 1 part 4% CuSO₄ to 49 parts bicinchonic acid) was mixed in a 96-well plate, covered and incubated at 25°C for 12 hours and assayed for absorbance at 562nm. Final concentrations for all samples were calculated compared to a standard curve of either Triglyceride Standard (Pointe Scientific, Ann Arbor, MI) or bovine serum albumin for protein standards. The number and age of flies assayed varied depending on experiment and are labeled in the figure legends.

For heart-specific assays, 15-30 individual hearts were exposed in 1xPBS. Excess fat and associated cells were removed from the sides of the heart using a finely pulled glass micro-pipette attached to a vacuum. Samples were washed 3 times with 1xPBS then dissected into 15-30 μ L of western lysis buffer. Samples were homogenized with a motorized pestle, briefly sonicated then incubated for 5 minutes at 70°C. Solutions were

treated as stated above to determine the final concentrations of heart-specific TG or protein. 9 such samples were analyzed per selection treatment.

Histology

Histological sections were obtained as previously described (Yu et al. 2013). Briefly, adult female flies (4-5 days post eclosion) were collected and placed in Telly's fixation buffer (60% ethanol, 3.33% formalin, 4% glacial acetic acid) for at least one week at 4°C prior to paraffin embedding. Serial 8-micron sections were stained with hemotoxin and eosin (H&E) then analyzed using a Leica DM2500 microscope equipped with a Leica DFC310FX digital camera. For each selection treatment, 3-5 serial sections from 13 animals were scored for the presence and degree of fat body accumulation between the heart and the dorsal cuticle. Data were analyzed using the Freeman-Halton extension of the Fisher's Exact Test with the R software package (R Core Team 2015). Images were cropped and annotated to demonstrate anatomical displacement.

Heart Structure

Hearts were dissected, stained and imaged as previously described (Alayari et al. 2009). Briefly, flies were dissected in oxygenated artificial hemolymph then the exposed hearts were chemically relaxed, fixed and stained with a 1:1000 dilution of GFP-conjugated phalloidin (Alexa Fluor®488 phalloidin, Grand Island, NY). Images were taken with a Zeiss Apotome in conjunction with the Axiovision software package. Image stacks were processed using the Fiji software package (Schindelin et al. 2012) to visualize the circumferential fibers of the cardiomyocytes. Images were randomly labeled and blindly

scored for structural defects. 25-32 hearts were scored per selection treatment and data were analyzed with Fisher's Exact Test using the R software package (R Core Team 2015).

Lipid Droplet Size

Adult flies, ~4-5 days old, were embedded in Tissue-Tek® O.C.T. Compound (Sakura® Finetek, Torrance, CA.), frozen, then cut longitudinally into 30µm sections using a Vibratome UltraPro™ 5000 Cryostat (The Vibratome Co. St Louis, MO.). When the cryostat approached the midline of the animal, sections were transferred to a glass slide and mounted in a medium containing 10µL Nile Red Stock Solution (0.1% w/v, Nile Red/acetone), 10µL Triton X-100, 5mL glycerol and 5mL 1xPBS. Samples were immediately imaged (<2 hours) using a Nikon A1R Confocal (Nikon Instruments Inc, Melville, NY) at 40x with a 1.5x digital zoom. Z-stacks were taken and used to generate maximum intensity projections. Lipid droplet size was quantified based off of previously described techniques (Wang et al. 2012). Briefly, the 5 largest droplets per section were measured for 2D area using the Fiji software package (Schindelin et al. 2012), for a total of 19 animals per selection treatment.

Statistical Analysis

All analyses were performed using either Statistica 7.1 software package (StatSoft Inc, Tulsa, OK.) or the R software package (R Core Team 2015). Fisher's Exact Test was used to quantify qualitative analyses and variations of a nested ANOVA were used where appropriate. Our standard model to compare the S and F populations is a nested ANOVA with selection regime and replicate population as independent variables with replicate

population nested within selection regime. Because the individual replicate populations are independent, they are treated as a random effect. In the case of the rescue experiments, the replicate populations were not independent as one replicate was split into either a control or rescued group. In this situation replicate was treated as a fixed effect. Statistics for the rescue experiments were generated by pairwise variations of the nested ANOVA's between the 3 groups (F, S, SR) with replicate population treated as a fixed or random effect where appropriate (Fig. 2.4B-H, Fig. 2.5B-E). Fisher's Exact Tests were performed in R. The standard test was used for the 2x2 contingency table generated when looking at heart structure (Fig. 2.6D), however the 2x3 contingency tables generated by the histological analysis required the Freeman-Halton Extension of Fisher's Exact Test (Fig. 2.3B).

2.4 Results

Selection for starvation resistance leads to a dilated heart phenotype.

To test whether selection for starvation resistance leads to cardiac dysfunction in *Drosophila melanogaster*, we employed two methods. First, we surgically exposed the hearts of adult flies in oxygenated artificial hemolymph in a denervated, purely myogenic state and recorded cardiac contractions using high-speed video microscopy (SOHA) (Karen Ocorr et al. 2007; K. Ocorr et al. 2007a; K. Ocorr et al. 2007b; Fink et al. 2009; Cammarato et al. 2015). End systolic and diastolic diameters of the heart wall were measured from these recordings at a defined point in the 2nd heart chamber in the A3 abdominal segment and used to calculate fractional shortening. Custom software (Fink et al 2009, sohasoftware.com) was used to analyze high-speed movies for the quantification of heart period (duration of each cardiac cycle), contraction intervals, arrhythmia and fractional shortening. We found no significant differences between the F and S populations for heart beat length (heart period, Fig. 2.1A), arrhythmia or contraction intervals (Fig. 2.2A-C). We observed an overall reduction in fractional shortening ($p < 0.03$), a measure of relative heart contractility, that was the result of a significant increase in the systolic diameter suggesting systolic dysfunction (Fig. 2.1A). The diastolic diameters also tended to be larger than the controls, although this increase did not reach statistical significance. Representative M-modes, which display heart wall movements over time, from the starvation-selected lines also demonstrated a dilated, less contractile heart with preserved systolic as well as diastolic intervals (Fig. 2.1C, bottom panel; Fig. 2.2B,C).

The *Drosophila* heart runs along the cuticle of the dorsal abdomen, tethered to the cuticle by sets of alary muscles. Many times upon dissection, we observed that the hearts in

the S lines were loosely bound to the dorsal cuticle and appeared distended due to large fat body deposits. These hearts would often detach from the cuticle during preparation and could not be used in the video analysis. Because this phenomenon was not observed in the F lines, we hypothesized that the abnormal heart parameters in the S lines represented the lower limits of heart dysfunction, since cardiac function in a subset of S flies could not be measured.

To validate our results with a complementary method, we performed optical coherence tomography (OCT), which measures heart function in intact flies, which includes innervation. OCT is a non-invasive, non-destructive imaging modality that produces image information similar to the M-modes obtained with SOHA (Fig. 2.1C,D), or to echocardiography in mammals, including humans (Wolf et al. 2006; Wolf and Rockman 2011). Although resolution is lower in OCT than in SOHA, OCT captured a more inclusive range of variation within the S populations, as it was not affected by the surgical limitations found in the S flies. Both end systolic and diastolic diameters, measured in this case at a defined point in the first heart chamber (conical chamber), were increased ($p < 3.3 \times 10^{-3}$, $p < 5.1 \times 10^{-3}$ respectively) (Fig. 2.1B), again resulting in an overall reduction in fractional shortening ($p < 6.8 \times 10^{-4}$). Similar to the findings of surgically prepared specimens, we found no significant changes in heart period (Fig. 2.1B). Transversely oriented M-modes provided a visual representation of the differences in end diastolic and systolic diameters (Fig. 2.1D).

Increased fat body mass physically interferes with the heart.

Alary muscles are responsible for anchoring the heart to the cuticle and assisting in relaxation during diastole (Klowden 2007). In the starvation-selected lines the alary muscles appeared to be compromised, presenting as a loose attachment of the heart to the dorsal cuticle upon dissection. This appeared to be caused by large deposits of fat body morphologically altering the position of the heart towards the ventral abdomen. To investigate this possibility, we performed histology and evaluated serial longitudinal sections of adult flies. Many S flies had gross anatomical displacement of the heart towards the ventral abdomen with large deposits of adipose tissue between the heart and the dorsal cuticle (Fig. 2.3A, right panel). Fat body deposits between the dorsal cuticle and heart were observed in ~85% of S flies compared to ~31% of F flies ($p < 0.02$) (Fig. 2.3B). Of the S flies with fat between the dorsal cuticle and the heart, ~27% had a severe phenotype where the heart was drastically distended towards the ventral abdomen (Fig. 2.3A, right panel). The severe phenotype was not observed in the F populations (Fig. 2.3B).

Heart dysfunction in the starvation-selected lines is dependent on increased fat storage.

Many phenotypic differences between the S and F lines are likely genetic, caused by alterations in allelic frequencies in response to selection for starvation resistance over many generations. These genetic differences may directly lead to heart dysfunction or may affect the heart as a secondary consequence of increased fat storage. To address this question, we performed experiments to decouple fat accumulation and heart dysfunction. In the first experiment, we transferred 4-day-old adults to non-caloric 1% agar for 7 days (Fig. 2.4A). After a week of starvation the “rescued” S lines (hereafter “SR”) had reduced TG levels compared to their age-matched S controls ($p < 1.2 \times 10^{-10}$) (Fig. 2.4B). TG levels in the

SR lines were not significantly different from the age-matched F controls suggesting that starvation for 7 days was sufficient to rescue the S lines from obesity. To investigate the relationship between fat storage and cardiac dysfunction, we measured heart parameters on the SR lines using SOHA and OCT. SOHA demonstrated that lean SR flies had lower diastolic and systolic diameters than their age-matched S controls ($p < 0.04$ and $p < 1.6 \times 10^{-4}$ respectively) (Fig. 2.4C and Fig. 2.4D) as well as increased contractility as measured through fractional shortening ($p < 1.4 \times 10^{-4}$) (Fig. 2.4E). While the end diastolic and systolic diameters failed to fully recover to F levels, fractional shortening levels in the SR lines were rescued, as they did not differ from the F controls ($p > 0.39$) (Fig. 2.4E). The OCT data largely supported the results obtained by SOHA. After a 7-day diet, SR flies had lower end diastolic and systolic diameters ($p < 1.5 \times 10^{-11}$ and $p < 3.3 \times 10^{-4}$ respectively) (Fig. 2.4F,G) as well as greater fractional shortening ($p < 2.1 \times 10^{-3}$) (Fig. 2.4H). Average diastolic diameter was higher in the S lines as compared to the age-matched F controls, but the data failed to reach significance ($p > 0.12$) (Fig. 2.4F). Differences in the absolute values between Figures 1 and 4 are likely a function of age and generations of selection.

Larval development time in the S populations is ~24 hours longer than in the F populations, during which they accumulate lipids available for adult starvation resistance (Reynolds 2013). In additional rescue experiments, we transferred S larvae to non-caloric 1% agar when the F larvae began to wander, to standardize larval feeding time (Fig. 2.5A). Adults were aged 4 to 5 days with food and assayed for heart dysfunction by SOHA. Rescued SR adults had lower TG content compared to the S controls ($p < 2.0 \times 10^{-7}$) and were not significantly different from the F flies (Fig. 2.5B). We found this improved the contractility of the heart to F levels as SR fractional shortening was significantly increased

compared to the S controls ($p < 1.1 \times 10^{-4}$) (Fig. 2.5E). This improvement in fractional shortening was a function of lower systolic diameter in the SR lines ($p < 0.04$) (Fig. 2.5D) as diastolic diameter was not different from the S controls ($p > 0.87$) (Fig. 2.5C).

Starvation-selected lines do not ectopically store lipids in the heart but instead increase storage capacity of lipids within the fat body.

Drosophila challenged with lipogenic diets store TG ectopically in non-adipose tissues such as the heart (Birse et al. 2010; Na et al. 2013). Intracellular lipid accumulation in the cardiomyocytes appears to disrupt myofibrillar architecture, and can lead to severe cardiac defects including partial conduction blocks, dysfunctional ostia and decreases in fractional shortening (Birse et al. 2010). To test the hypothesis that heart dysfunction in the S lines is caused by intracellular fat accumulation, we dissected hearts and measured their TG contents in F and S flies. Despite higher whole-body levels of TG in the S flies ($p < 0.03$) (Fig. 2.6A), we found no significant changes in heart-specific TG levels (standardized to total heart protein, $p > 0.84$), indicating no difference in cardiac lipids between the S and F lines (Fig. 2.6B). Intramyocardial lipid deposition is further hypothesized to lead to structural changes in the myofibrillar architecture of the cardiomyocytes (Birse et al. 2010; Lim et al. 2011). To address this possibility we examined hearts for gross structural changes. Adult hearts were surgically exposed and stained with GFP-conjugated phalloidin to visualize the actin fibers of the cardiomyocytes. We found low levels of myofibrillar disruption in the cardiomyocytes of both the F and S flies, but quantitatively the frequency of disruption was not significantly different (Fig. 2.6D) ($p > 0.21$).

The S populations harbored higher whole body TG ($p<0.02$) (Fig. 2.7A), but total protein levels were not significantly different from the F controls ($p>0.54$) (Fig. 2.7B). Despite comparable protein levels, S flies have visibly large, distended abdomens (Masek et al. 2014) and during dissection we observed extensive fat body tissue in the S abdomen. Adipose tissue has a limited storage capacity for fats and the fat-mediated lipotoxic effects on the heart have been attributed to conditions when lipids are in excess of storage capacity. We hypothesized that the S lines had adapted to starvation selection by increasing TG storage capacity within the fat body. We examined lipid droplets within the fat body using Nile Red staining. In the S lines, longitudinal sections of the fat body near the dorsal cuticle had large lipid droplets (Fig. 2.6E, bottom panel). The area of the largest droplets was approximately 65% larger than the area of the largest lipid droplets from the F populations ($p<0.04$) (Fig. 2.6F). This corresponded to an approximate 117% increase in lipid droplet volume.

2.5 Discussion

*Obesity associated heart dysfunction in starvation-selected *Drosophila*.*

Many recent studies have demonstrated the merits of using *Drosophila* as a model to study the genetics and physiology of obesity-induced heart dysfunction (Birse et al. 2010; Lee et al. 2010; Lim et al. 2011; Sujkowski et al. 2012; Na et al. 2013; Diop et al. 2015). Here we present the first study to investigate the effects of obesity on the heart in laboratory-evolved populations. We found that long-term laboratory selection for starvation resistance leads to obese flies with a correlated tradeoff in heart function. Using independent methods we demonstrated that starvation-selected hearts are dilated and less contractile than their unselected controls.

While the data from SOHA and OCT largely agree, there are some important technical differences that affect their individual interpretation. The surgical preparation required for SOHA severs the ventral thorax and head from the abdomen, eliminating the effects of neurogenic innervation on the heart from the central nervous system, leaving a purely myogenic heart that will beat for hours in oxygenated artificial hemolymph. Therefore these data are useful in understanding the myogenic properties of the heart. On the other hand, OCT is an *in vivo* assay that measures the heart parameters of adult flies which have their entire nervous system intact. These differences are observed in the data as heart rate in OCT is nearly 4 times larger than with SOHA (Fig. 2.1) which may be expected in a neurologically innervated versus completely myogenic heart (Brooks and Lange 1977) and has been documented in *Drosophila* (K. Ocorr et al. 2007a). Because of the unique physiology of the S populations, we lost many S hearts during dissection for SOHA which may have limited our ability to statistically resolve the increased diastolic

diameter observed in the OCT data. Furthermore, the surgical preparation for SOHA requires the partial removal of fat body to better visualize the heart. By removing this tissue, this procedure may provide a slight, acute improvement in contractility, leading to reduced differentiation between the F and S populations. Despite their inherent differences, both methods consistently agreed on the relative differences in diameter and contractility between the F and S populations.

The genetic basis of heart dysfunction in starvation-selected Drosophila is correlated with disrupted lipid homeostasis.

The genetic basis of heart dysfunction in the S lines could be due to pleiotropic effects of starvation-selected alleles, which directly affect the development or structure of the heart. Many genetic mechanisms could explain maladaptive heart phenotypes in the context of selection for starvation-resistance. For example, linkage disequilibrium (LD) between positively selected starvation-resistance genes and heart-specific loci could have caused increased frequency of particular alleles with direct negative effects on the heart. Alternatively, rearing flies in small cages with plentiful food and lack of predation, may have lifted selective restraints on the heart, allowing genetic drift towards dysfunction. In addition, selected alleles may have tissue-specific effects with alleles favoring starvation-resistance in one tissue causing off-target effects in other cell types like the heart, which may not be crucial to starvation survival. Conversely, starvation-selected alleles may affect the heart as a secondary consequence of disrupted lipid homeostasis. Our data support the latter, as we demonstrated that heart function could be improved by reducing total TG through a 7-day starvation period. We interpret these findings to suggest that heart

dysfunction is not caused by alleles which directly disrupt the development or function of the heart, but by a fat-dependent mechanism.

One of the most important factors leading to obesity-associated heart dysfunction in *Drosophila* is cardiac steatosis (Birse et al. 2010; Lim et al. 2011; Sujkowski et al. 2012; Na et al. 2013; Diop et al. 2015). Our data suggest this is not the case in starvation-selected *Drosophila*, as these flies do not ectopically store TG in the heart. Instead we believe starvation-selected *Drosophila* have adapted to the extreme context of their ecology by increasing the storage capacity of lipids within their fat body. Histological analysis confirmed the presence of expansive fat body tissue in the S lines, and further examination revealed this tissue contained large lipid droplets. The expanded tissue morphologically altered the proper anatomical placement of the heart along the dorsal cuticle. Our data suggest that this physical interference contributes to heart dysfunction in the S lines.

An alternative mechanism for obesity-induced heart disease is the chronic inflammation of adipose tissue leading to changes in cytokine production and cellular signaling in responding tissues (Wang and Nakayama 2010; Sun et al. 2012). Cross talk between the fat body and other organs has been well documented in *Drosophila* (Agaisse and Perrimon 2004; Bai et al. 2012; Rajan and Perrimon 2012; Andersen et al. 2013). Our data do not exclude the possibility that the fat body is inflamed in the S populations, leading to changes in fat body-heart signaling. This intriguing possibility requires further investigation that is beyond the scope of the current study.

Perspectives and Significance

Many theories have been proposed to explain the evolutionary origins of obesity in

humans (Genné-Bacon 2014). Of many interesting ideas, our data are consistent with the thrifty genotype hypothesis, which argues that genetic variants which promote the efficient utilization and storage of nutrients are selected for during periods of famine and starvation (Neel 1962). While this theory has faced criticism (Speakman 2008; Stöger 2008; Hales and Barker 2013) it is important to note its plausibility in the context of extreme selection pressures across repeated generations in our starvation selected populations, which are unmatched in the anthropological record. Other theories argue that epigenetic factors may play a role in driving obesity, as gene/environment interactions in the womb may lead to changes in chromatin structure (Stöger 2008). This has recently been supported in *Drosophila* as both maternal and paternal high-sugar diets have been shown to cause transgenerational effects on metabolism and macronutrient homeostasis (Buescher et al. 2013; Öst et al. 2014). However, our preliminary tests have revealed no such parental effects on lipid storage, fecundity or starvation-resistance in our populations (data unpublished, Gibbs A.G.). In addition our flies are removed from selection for one generation and reared with identical environmental conditions as the F populations prior to each experiment. This suggests that genetics plays the primary role in the evolved characteristics of the S populations.

In mammals it is hypothesized that a larger capacity to store fats in subcutaneous adipose tissue (SAT) limits the harmful effects of ectopic fat deposition in other tissues (Bastien et al. 2014). This helps explain why low SAT levels in individuals with lipodystrophic disorders leads to high levels of ectopic fat accumulation and metabolic disorders (Nelson et al. 2013; Nolis 2014). Selection on genetic variants that increase the storage capacity of adipose tissue may then be an adaptive response to provide the

organism with a larger reservoir to store neutral fats. Evidence for the protective role of adipose tissue has been demonstrated in *Drosophila*, where the fat body has been shown to protect against hyperglycemia in response to a high-sugar diet by switching to a lipogenic expression profile (Musselman et al. 2013). In nature the ability to store excess lipids in adipose tissue may provide a protective buffer against periods of famine while also avoiding metabolic disorders caused when fats are stored ectopically. Counter-selective forces (eg. predation, decreased mobility) that result in decreased dispersal ability or increased predation, would likely balance allelic frequencies to an adaptive state. In our experiments some of these counter forces are removed, reducing selective restraint against increased adipose storage capacity. This resulted in S flies that store so much fat that the tissue appears to physically interfere with the normal function of the heart. This unique mechanism of adaptation may provide S flies with increased energy reserves vital to survive starvation while dampening the lipotoxic heart phenotype traditionally associated with obesity. It will be interesting to further examine this hypothesis and test whether the S populations are resistant to other lipotoxic phenotypes traditionally associated with obesity - including insulin resistance and reduced longevity - in future studies.

Figure 2.1. Starvation-selected hearts are dilated and less contractile than their unselected controls. (A) Heart parameters measured by semi-automated optical heartbeat analysis (SOHA), showed that the S populations have higher systolic diameter ($p < 0.05$), trending but not statistically significantly higher diastolic diameter ($p > 0.06$), lower fractional shortening ($p < 0.03$) and no difference in heart period ($p > 0.86$) compared to the F populations. Nested ANOVA, $N = 57-74$ (B) Heart parameters measured from optical coherence tomography (OCT) largely agreed with SOHA as S populations showed higher systolic diameter ($p < 3.3 \times 10^{-3}$), higher diastolic diameter ($p < 5.1 \times 10^{-3}$), lower fractional shortening ($p < 6.8 \times 10^{-4}$) and no difference in heart period ($p > 0.14$). Nested ANOVA, $N = 42-68$. Representative M-modes where the Y-axis is a 1 pixel width slice of the original video viewed over time (x-axis) in either (C) SOHA or (D) OCT demonstrate a S heart which is dilated and less contractile than the F controls.

Figure 2.2. Starvation-selected *Drosophila* show no difference in contraction intervals or arrhythmia index. The S populations showed no difference in (A) Arrhythmia Index ($p>0.21$) (B) Diastolic Interval ($p>0.92$) or (C) Systolic Interval ($p>0.49$) compared to their unselected controls. Nested-ANOVA, $N=57-74$.

Figure 2.3. Fat body physically interferes with the starvation-selected heart. (A) Longitudinal histological sections (H&E stain). The asterisk indicates the lumen of the conical chamber of the heart, “T” indicates location of the thorax and the red arrows point to fat body deposits. Normal sections (left panel) show the heart closely associated with the dorsal cuticle. Moderate sections (center panel) have small deposits of fat body between the dorsal cuticle and heart. Severe sections (right panel) have large fat body deposits between the heart and dorsal cuticle. (B) Starvation-selected lines have higher instance of Moderate and Severe phenotypes ($p < 0.02$). Fisher’s Exact Test (Freeman-Halton Extension), $N = 13$.

Figure 2.4. The heart phenotype can be partially rescued through a week-long diet (A) Experimental design: A cohort of the starvation-selected lines were made lean ("SR" Group) by a week-long diet of 1% non-caloric agar. (B) The diet significantly reduced total TG's compared to the age-matched S control lines ($p < 1.2 \times 10^{-10}$, $N=24$) and were non-significantly different from the F lines. Results from SOHA showed SR populations had correlated improvements in (C) systolic and (D) diastolic diameters as well as (E) improved fractional shortening as compared to the S populations. ($p < 1.6 \times 10^{-4}$, $p < 0.04$ and $p < 1.4 \times 10^{-4}$, respectively, $N=45-46$). OCT measurements showed SR populations had correlated improvements in (F) systolic and (G) diastolic diameters as well as (H) improved fractional shortening as compared to the S populations. ($p < 3.3 \times 10^{-4}$, $p < 1.5 \times 10^{-11}$ and $p < 2.1 \times 10^{-3}$, respectively, $N=44-45$). Differing letters 'a', 'b' and 'c' denote significant differences between groups ($p < 0.05$). Pairwise nested ANOVAs (F vs S, F vs SR, S vs SR) were used for these assays (see methods for details).

Figure 2.5. The heart phenotype can be partially rescued by removing nutrient sources during extended larval development in the S lines. (A) Experimental design: S flies are deprived of nutrients during their extended larval feeding period. This standardizes their nutrient availability to that of the F lines leading to (B) reduced total TG/fly in the rescued S (SR) populations ($p < 2.0 \times 10^{-7}$). Nested ANOVA, $N=18$. (C) The treatment did not affect diastolic diameter ($p > 0.87$), however (D) systolic diameter was significantly reduced in the S populations ($p < 0.04$) leading to (E) an overall improvement in contractility as measured through fractional shortening ($p < 1.1 \times 10^{-4}$). Pairwise nested ANOVA, $N=53-58$. Differing letters 'a', 'b' and 'c' denote significant differences between groups ($p < 0.05$).

Figure 2.6. Starvation Selected Lines resist ectopic lipid storage in the heart. (A) The S populations store higher whole body levels of TGs than the F populations ($p < 0.03$, standardized to total protein). Nested ANOVA, $N = 24$. (B) The excess lipids in the S populations are not ectopically stored within the heart ($p > 0.84$, standardized to total heart protein). Nested ANOVA, $N = 9$. (C) We then screened for disrupted myofibrils in our populations. Normal circumferential fibers (Top Panel) are oriented vertically, perpendicular to the heart tube. Disrupted fibers (Lower Panel) have gaps between these fibers. (D) We found low levels of disruption in both F and S populations, however no difference between selection treatments ($p > 0.21$). Fisher's Exact Test, $N = 25-32$. (E) We stained the lipid droplets of the adult fat body in the F and S populations with Nile Red. (F) The 2-dimensional area per lipid droplet was on average much larger in the S populations ($p < 0.04$). Nested ANOVA, $N = 19$.

Figure 2.7. Whole Body TG and Total Protein Levels. (A) The S populations have higher levels of whole body TG than F populations ($p < 0.02$). (B) There were no differences in whole body protein levels between the S and F populations ($p > 0.54$). Nested ANOVA, $N=24$.

Author Contributions: C.M.H. and A.G.G planned experiments and wrote the paper with assistance from all other authors. K.M.L. and C.M.H. prepared genomic DNA, oversaw library prep and maintained data storage. M.H. and C.M.H. designed and executed alignment pipeline. M.B. and C.M.H. performed intra-replicate genetic correlations, designed code to measure genome-wide heterozygosity and graphing. L.E. and C.M.H. designed drift filter and statistical analysis. K.M.L. and C.M.H. designed molecular pathway diagram. All other experiments were performed by C.M.H. Each author contributed to editing the final manuscript.

3.1 Abstract

Experimental evolution affords the opportunity to investigate adaptation to stressful environments. Studies combining experimental evolution with whole-genome resequencing have provided insight into the dynamics of adaptation and a new tool to uncover genes associated with polygenic traits. Here, we selected for starvation resistance in populations of *Drosophila melanogaster* for over 80 generations. In response, the starvation-selected lines developed an obese condition, storing nearly twice the level of total lipids than their unselected controls. While these fats provide a ~3-fold increase in starvation resistance, the imbalance in lipid homeostasis incurs evolutionary cost. Some of these tradeoffs resemble obesity-associated pathologies in mammals including metabolic depression, low activity levels, dilated cardiomyopathy and disrupted sleeping patterns. To determine the genetic basis of these traits we resequenced genomic DNA from the selected lines and their controls. We found 1,046,373 polymorphic sites, many of which diverged between selection treatments. Additionally, we found a wide range of genetic heterogeneity between the replicates of the selected lines, suggesting multiple mechanisms of adaptation. Genome-wide heterozygosity was low in the selected populations, with many large blocks of SNPs nearing fixation. We found loci under selection by generating an algorithm to control for the effects of genetic drift. These loci were mapped to a set of 1,453 genes, which were associated with morphogenesis, development, tissue differentiation and regulation of metabolism. The results of our study speak to the evolutionary origins of obesity and provide new targets to understand the polygenic nature of obesity in a unique model system.

3.2 Introduction

Natural selection drives organisms to adapt to a wide variety of stressors which are dynamic across evolutionary time. Investigating the mechanistic basis of these adaptations has fundamentally transformed modern science and medicine (Hodgkin and Huxley 1952; Chien et al. 1976; Krebs and Johnson 1980). A complimentary approach to studying uniquely adapted organisms in nature is to simulate evolution in the laboratory, where investigators mimic selective pressures an organism may face in the wild with highly controlled, replicated designs (Bennett 2003). Traditionally, experimental evolution has been a powerful tool in testing theories of evolution and understanding the physiological basis of adaptation to novel environments (Garland and Rose 2009; Kawecki et al. 2012).

Recently, experimental evolution has been elevated by the increased accessibility of next-generation sequencing, which has provided insight into the genetic basis of adaptation on a genome-wide level. The “Evolve and Resequence” (E&R, Turner et al. 2011) strategy has been frequently implemented in work with *Drosophila*, where researchers have analyzed whole-genome datasets for a variety of selected traits including hypoxia tolerance (Zhou et al. 2011), longevity (Remolina et al. 2012), courtship song (via interpulse interval; Turner and Miller 2012), body size (Turner et al. 2011), desiccation resistance (Kang et al. 2016), development time (Burke et al. 2010), temperature tolerance (Orozco-terWengel et al. 2012) and resistance to both the parasitoid *Asobara tabida* (Jalvingh et al. 2014) and the *Drosophila* C virus (Martins et al. 2014). While future improvements in experimental design promise to increase the power to detect adaptive loci (Baldwin-Brown et al. 2014; Kofler and Schlotterer 2014; Kessner and Novembre 2015), studies of existing selected *Drosophila* populations have done a great deal to describe the genomic topography of

laboratory-selected phenotypes. They provide evidence that adaptation is driven by standing genetic variation (Burke et al. 2010), and they also find evidence for multiple temporal trajectories for alleles under selection (Orozco-terWengel et al. 2012; but see Burke and Long 2012). Regions of the genome that change in frequency following laboratory selection may harbor adaptive polymorphisms; genes at or near these candidate alleles have been associated with selected traits (Burke et al. 2010; Turner et al. 2011; Zhou et al. 2011; Orozco-terWengel et al. 2012; Remolina et al. 2012; Turner and Miller 2012; Jalvingh et al. 2014; Martins et al. 2014; Kang et al. 2016). Consigning causality to candidate loci remains challenging as linkage disequilibrium may increase in experimentally evolved populations of *Drosophila* (Teotónio et al. 2009; Franssen et al. 2015). While this may inflate the number of loci detected under selection, techniques to discriminate causal variants are available in *Drosophila*. There have been many E&R studies in other species (reviewed in: Kawecki et al. 2012; Long et al. 2015), however *Drosophila* is particularly well suited for evolution experiments due to its reasonably short generation times, low maintenance costs and genetic tractability. In addition, the relative genetic similarity between flies and mammals provides promise for translational impact (Reiter et al. 2001).

Here, we performed an E&R study on populations of *Drosophila melanogaster* that were selected for starvation resistance for 83 generations. In response to this selection regime, the starvation-selected lines have evolved an obese condition, storing nearly 2 times the levels of total lipids as compared to their unselected controls (Reynolds 2013; Figure 1A). They metabolize these fats when starved, allowing them to live ~11-14 days without food which is 3-4 times longer than the unselected controls. Obesity in these

populations is largely driven by a developmental delay during the 3rd larval instar (Reynolds 2013). This delay provides time for the selected lines to acquire excess nutrients, which are synthesized into lipids as nutrient deprivation during this window has been shown to reduce whole body triglycerides to control levels in adult flies (Masek et al. 2014; Hardy et al. 2015). The selected populations are also adapted to maintain high fat stores as adults, presenting with high whole body triglyceride levels at 4 and 11 days post-eclosion despite consuming fewer overall calories (Masek et al. 2014; Hardy et al. 2015). The starvation-selected populations are genetically programmed to store and retain fat, which comes with many evolutionary costs. The tradeoffs associated with disrupted lipid homeostasis range from depressed metabolic rate accompanied by low activity levels and poor flight performance to low fecundity, dilated cardiomyopathy and excess sleep (Brewer 2013; Reynolds 2013; Masek et al. 2014; Hardy et al. 2015). Many of these phenotypes are reminiscent of other *Drosophila* models of obesity (Birse et al. 2010; Na et al. 2013) and are also characteristic of metabolic disorder in mammals.

To understand the genetic basis for these complex phenotypes we sequenced pooled genomic DNA from replicate populations of both the starvation-selected and unselected lines. We found many polymorphisms at dissimilar frequencies between the replicate populations of selected lines, which correlated with phenotypic differences in starvation resistance. Genome-wide levels of heterozygosity showed strong signatures of selection, with many large regions of the genome approaching fixation, which were fairly inconsistent across selected replicates. Despite heterogeneity among replicate populations, the differences in allelic frequencies between selective treatments were much higher. To look for conserved mechanisms of adaptation in response to selection, we developed an

algorithm to filter polymorphisms that may be divergent due to genetic drift. After filtering for drift, we mapped the remaining loci to a set of 1,453 genes which were conserved across replicate populations. We found enrichment for genes involved in many pathways including regulation of metabolism, with a high number of genes associated with the insulin and adipokinetic hormone signaling network. The human orthologs for these genes were involved in a host of mammalian diseases including myopathy, cardiomyopathy and type-2 diabetes.

From an evolutionary perspective, our study is consistent with the thrifty gene hypothesis, an evolutionary theory of obesity in which alleles that increase nutrient storage and dampen utilization are selected for during periods of famine (Neel 1962). Here we provide a list of such candidate genes, which can be functionally validated and used as targets for future research.

3.3 Results

Genetic heterogeneity between the replicates of the starvation-selected populations correlates with differences in starvation resistance.

After the 83rd generation of starvation selection we resequenced genomic DNA from pools of 100 females for each of the 3 starvation-selected populations (hereafter “S” populations “A-C”) and their 3 unselected fed controls (hereafter “F” populations “A-C”; see Methods for detailed evolutionary history; outlined in Figure 3.1B). The raw sequence reads were mapped and filtered for quality control, resulting in a set of 1,046,373 polymorphisms across all 6 populations (F_{A-C}, S_{A-C}; Methods). We performed a principal component analysis (PCA) to visualize the relationships between populations with respect to reference allele frequency. The analysis resulted in 6 principal components, with the first 3 explaining a combined 88.0% of the variation in allele frequency between populations (Appendix A Table S3.1). The F populations clustered tightly together, separated from the S populations, suggesting an overall effect of selection on allele frequency (Figure 3.2A-C). However the S populations appeared more variable, with the SA replicate clustering independently from the SB and SC populations. We quantified the observed PCA trends by calculating the Pearson product-moment correlation coefficient (r) with respect to reference allele frequency between all 6 populations in a pairwise manner (Figure 3.2D, Appendix A Figure S3.2C-D). Correlations in allele frequencies between the F and S populations were relatively low ($r = 0.45$ - 0.54 , lower left quadrant, Figure 3.2D) compared to correlations within F replicate populations ($r = 0.71$ - 0.82 , upper left quadrant, Figure 3.2D), consistent with a strong effect from the selection treatment. We also found relatively low correlation of allele frequencies between the selected replicate populations ($r = 0.45$ -

0.71, lower right quadrant, Figure 3.2D), compared to intra-population correlations in the F populations ($r = 0.71-0.82$). This was largely due to poor correlation of the SA population with the other S populations (SAxSB, $r = 0.45$; SAxSC, $r = 0.45$) while SB and SC maintained higher relative correlation ($r = 0.71$). All correlations were statistically significant with Bonferroni adjusted p-values less than 2.0×10^{-16} (Appendix A Figure S3.1D).

Next we wanted to test if genetic variation between the S populations correlated with differences at the organismal level. To do this we measured starvation resistance in the S populations. On average, SA females survived starvation for 344.6 ± 4.7 hours, a 25.8–29.4% increase in duration over SB and SC females (SB: 266.3 ± 4.2 hours, $p < 2.0 \times 10^{-16}$; SC: 274.0 ± 4.7 hours, $p < 2.0 \times 10^{-16}$, Figure 3.3A). Similarly, SA males survived an average of 283.7 ± 3.9 hours of starvation, 20.5–31.6% longer than their sex matched SB and SC controls (SB: 215.5 ± 3.5 hours, $p < 2.0 \times 10^{-16}$; SC: 235.4 ± 4.2 hours, $p < 2.0 \times 10^{-16}$, Figure 3.3B). We found the SB and SC populations were more similar in starvation survival with no significant difference between SB and SC females ($p > 0.46$, Figure 3.3A) and a relatively small 9.3% increase in starvation survival in SC over SB males ($p < 1.2 \times 10^{-3}$, Figure 3.3B).

Genome-wide heterozygosity levels provide evidence for strong selective sweeps.

During natural selection, advantageous loci and regions within linkage disequilibrium increase in frequency leading to localized reduction in variance marked by low levels of heterozygosity (Burke 2012). To study the regional effects of selection in the S populations, we calculated average heterozygosity for blocks of SNPs within a 100 kb sliding window with a step size of 2000 bases across the genome. The F populations demonstrated fairly consistent genome-wide levels of heterozygosity (black lines, Figure

3.4A-C), as average block heterozygosity was equal to 0.30-0.32 (Figure 3.4D) with low variance, ranging from 1.3×10^{-3} to 1.6×10^{-3} between populations (Figure 3.4E). The S populations however displayed many regional declines in heterozygosity (red lines, Figure 3.4A-C), which presented in lower average block heterozygosity (0.21-0.23, $p < 2 \times 10^{-16}$, Figure 3.4D) and a 4.4-4.9 fold increase in variance over the F populations ($p < 2.2 \times 10^{-16}$, Figure 3.4E).

In some instances we found regions of the genome approaching fixation, as we discovered 1,983-3,184 100 kb blocks in the S populations with less than 0.05 average heterozygosity and no more than 4 in any F population (Appendix A Figure S3.2A). Many times these 100 kb blocks overlapped and clustered together into contiguous sequences. For each population (S_{A-C}) we found 17-30 contiguous blocks of low heterozygosity (Figure 3.5A) which averaged 321 ± 38 kb (S.E.M.) in length and ranged from 104 to 2,120 kb (Figure 3.5B). We looked for overlapping regions of these contiguous blocks across replicates to look for any repeatable signatures of selection (Figure 3.5C). While many of the blocks were associated with a specific population, we did find 4 regions across chromosomes X, 3L and 3R which had low heterozygosity (< 0.05) across all replicates which ranged from 72-176 kb (bottom row, Figure 3.5C). We found a set of 12 previously characterized genes within these windows and 36 in total (Appendix A Table S3.2). These genes did not cluster into any significant gene ontology categories.

Finding polymorphisms that are consistent with selection

Troughs in heterozygosity are indicative of selection favoring a variant and “sweeping”, or reducing, neutral variation linked to the selected locus. However, alleles

associated with complex traits in sexual species may respond to selection through incomplete sweeps and/or dynamic trajectories that do not involve fixation (Burke 2012). Such loci may be difficult to distinguish from those which have changed in frequency due to genetic drift. In order to find loci that were consistent with selection we developed an algorithm to filter SNPs whose difference in allele frequency between selection treatments could be explained by genetic drift. The algorithm models the work of Motoo Kimura, using a diffusion model (Eq. 3.1) to describe genetic drift (Supplemental Code, Kimura 1955). While Kimura's diffusion approximation has been used to model drift elsewhere (Stemshorn et al. 2011), to our knowledge it has not been adapted for use in E&R studies.

Equation 3.1

$$\phi(p, x; t) = \sum_{i=1}^{\infty} p(1-p)i(i+1)(2i+1)F(1-i, i+2, 2, p)F(1-i, i+2, 2, x)e^{-\frac{i(i+1)t}{4Ne}}$$

Given the number of generations (t), effective population size (Ne) and initial allele frequency (p), the algorithm generates a posterior probability distribution of allele frequency due to drift. Kimura's equation requires the Gauss hypergeometric function $2F1$, which was calculated using the `hyp2f1` function from SciPy (Release 0.14.0). We found that 50 summations, $\sum_{i=1}^{50}$, and $x=1000$ was sufficient sampling to generate an appropriate distribution with adequate speed.

Next we needed to define the parameters (t, Ne, p) for the starvation-selection experiment. Here, we used $t = 154$ generations as replicates were split for 70 generations prior to the 83 generations of selection for starvation resistance plus the generation removed from selection (See detailed phylogeny in Figure 3.1B). Effective population size

was then estimated by measuring the variance in allele frequency between the unselected (F_{A-C}) populations, using the 1,046,373 quality control filtered SNPs and the theoretical equation for variance in allele frequency after t generations (Eq. 3.2; Templeton 2006).

Equation 3.2

$$Var(p_t) = p(1 - p) \left[1 - \frac{1}{2Ne} \right]^t$$

We grouped SNPs whose average minor allele frequency across populations F_{A-C} was equal when rounded to the nearest hundredth and calculated the variance of each bin. We then calculated Ne for each bin, using the bin's associated allele frequency $p = \{0.0, 0.01, 0.02 \dots 0.50\}$ and $t = 154$ generations. Variation calculated from low allele frequency bins ($p < 0.07$) was much lower than from higher frequencies, which led to suspiciously high Ne values (Figure 3.6A). However, the bias quickly resolved towards a stable estimate at allele frequencies greater than 0.07. Because of this bias we took the median Ne from all 51 bins. From the data we calculated effective population sizes of 972 for autosomes and 748 for the X chromosome. We believe these estimates are reasonable given the census population size of ~2000 individuals (Methods). Furthermore, the X to Autosome N_e ratio of ~0.77 is consistent with the theoretical 0.75 ratio, given no evidence of a sex bias in our populations.

We used Kimura's equation described above using parameters $t = 154$ and $Ne = \{972|748\}$ for each starting allele frequency $p = \{0.01, 0.02, 0.03 \dots 0.50\}$. For each value of p we obtained a probability distribution of allele frequencies, which described the

likelihood of posterior allele frequencies due to genetic drift from 0 to 1 (Figure 3.6B). We randomly sampled from these probability distributions to perform simulations of genetic drift. Specifically, for each value of p we simulated 2 populations under drift by generating a set of 3.0×10^7 values for each population by randomly sampling from its associated probability distribution. We then calculated the absolute difference between the indices of both sets, creating a distribution of absolute difference in allele frequency between two populations under drift (Figure 3.6C). We calculated the 99.999% quantile of each distribution to observe extreme absolute changes in allele frequency (Figure 3.6C). The 99.999% value became the 'Drift Threshold', which was calculated for each value of p , to generate a curve which described the relationship between starting allele frequency and the maximum allele frequency difference expected between 2 populations by drift (Figure 3.6D). To corroborate our approach, we adjusted the number of simulations in our algorithm to match the first 13,000 runs of a forward simulation of genetic drift (Appendix A Figure S3.3A). We found a high degree of similarity between our algorithm and the forward simulation (Appendix A Figure S3.3B-C, autosomes: $r^2 = 0.96$, $p < 5.9 \times 10^{-36}$; X: $r^2 = 0.93$, $p < 4.5 \times 10^{-29}$).

Starting allele frequency for each SNP was estimated as the average minor allele frequency across F replicates. This value was rounded to the nearest hundredth and used as the starting allele frequency to find the Drift Threshold for that SNP. If the absolute difference in allele frequency between the independent replicates (ie. $|MAF_{FA} - MAF_{SA}|$) was less than the Drift Threshold, the SNP was discarded. We were therefore 99.999% confident that the remaining SNPs were not different between the F and S populations due to drift.

Selection converges on biological processes despite low SNP-level repeatability.

After filtering for drift we were left with 37,062, 45,506 and 61,370 high-quality SNPs for replicates A, B and C whose differences between selection treatments were consistent with selection. We plotted the absolute difference in minor allele frequency between the F and S populations for all SNPs across the genome and found many peaks across all 3 replicates (red points, Figure 3.7A-C). We mapped SNPs from each population (S_{A-C}) to genomic features, including total gene region, introns, exons, promoter regions (1kb up or down stream) and intergenic regions. We found a nearly identical distribution of SNPs by genomic feature across populations (Figure 3.8A). In total we found 120,764 SNPs represented by 1 or more populations. Out of this set, only 1,796 SNPs (1.5%) were conserved across all populations, with 99,386 (82.3%) associating within a single population (Figure 3.8B). The remaining 19,582 SNPs associated with pairs of populations, the bulk of which (15,285) were shared between the SB and SC population. The SA population had fewer SNPs in common with the SB and SC populations, sharing just 1,501 and 2,796 SNPs respectively, consistent with our previous measurements of low allelic correlation (Figure 3.2).

We then wanted to test if SNPs at different loci across populations were found in similar genes and potentially performing similar functions. To do this we compiled non-redundant lists of genes for each population. If within a given population, more than 1 SNP was associated with a gene, that gene was counted once. We found 4,232, 4,826 and 5,815 genes for each respective population (S_{A-C}) for a total of 8,891 genes across populations. In total 1,453 genes (16.3%) were found to have at least one SNP in all 3 replicate populations. Again we found more genetic similarity between the SB and SC populations as

they shared 1,657 genes compared to 555 or 864 between SA and the SB or SC populations, respectively (Figure 3.8C).

We interpreted the higher fraction of conserved genes (16.3%) to SNPs (1.5%) to indicate selection may be acting on similar genetic networks, despite acting on dissimilar loci. To further explore this hypothesis, we analyzed gene ontology enrichments for the population-level gene sets. In total we found 261, 290 and 202 GO terms within each population for a total of 341 unique terms. 163 (47.8%) of these terms were conserved across S_{A-C} , with ~73% found in at least 2 replicates, suggesting that selection may have acted on more similar mechanisms of adaptation than may have been predicted from the low level of SNP conservation (Figure 3.8D).

The central mechanisms of adaptation are related to a wide variety of cellular processes including morphogenesis, development, tissue differentiation and regulation of metabolism.

We focused on characterizing the set of 1,453 genes that were conserved across S_{A-C} (Figure 3.8C), to understand how they may contribute to adaptation. We performed gene ontology enrichment and found 668 GO terms with a Benjamini-Hochberg corrected p-value < 0.05 . We controlled for false positives within our list using GO-Module (Yang et al. 2011), and re-adjusted our significance threshold to 5×10^{-3} , leaving us with a set of 370 enriched terms (Appendix C Supplementary Gene Ontology Table). The set of 1,453 genes was enriched for a broad range biological processes, with the top categories largely involving morphogenesis, development and differentiation (Table 3.1). In addition to these major groupings we found enrichment for genes associated with processes which have been previously identified in the S populations (Table 3.1). For instance, the S populations

have low metabolic rates and increased lipid stores which correlate with gene enrichments for several categories related to metabolism, including regulation of both metabolic process and macromolecule biosynthetic process (Table 3.1, Appendix C Supplementary Gene Ontology Table). Furthermore, enrichment for genes involved in locomotion, behavior, sleep, oogenesis, female gamete generation and heart development correlate with the low activity levels, poor flight performance, disrupted sleep patterns, altered foraging behaviors, poor fecundity and heart dysfunction previously reported in the S populations (Table 2, Brewer 2013; Reynolds 2013; Masek et al. 2014; Hardy et al. 2015).

Because *Drosophila* and humans share a high degree of genetic similarity (Reiter et al. 2001), we wanted to examine the predicted function of the starvation-selected gene orthologs in humans. To do this we converted the set of 1,453 genes to their corresponding human orthologs and looked for disease enrichments. We found that 1,041 of the 1,453 starvation-selected genes were conserved in humans, which mapped to a set of 2,846 human orthologs due to the increased levels of genetic redundancy in higher metazoans. For instance, the *Drosophila* gene *Sprouty-related protein with EVH-1 domain* (*sprd*) has 3 human orthologs (*SPRD1*, *SPRD2* and *SPRD3*). Genes from the ortholog set were enriched in several human disease categories including myopathy, cardiomyopathy, type-II diabetes, leukemia, dilated & hypertrophic cardiomyopathy and osteoporosis (Table 3.2).

3.4 Discussion

Here we report the first E&R study to look at the genome-wide effects of experimental selection for starvation resistance in *D. melanogaster*. We found 1,046,373 polymorphic sites across populations F_{A-C} and S_{A-C} with 120,764 unique loci whose frequency diverged greater than expected by drift between selection treatments. Allelic frequencies at these loci varied between S_{A-C} , although genetic dissimilarity on the SNP level converged on higher order processes, as SNPs across populations S_{A-C} clustered into similar genes within conserved ontology categories. Here we discuss the evolutionary forces driving genetic adaptation to starvation resistance, highlight the allelic response to genes involved in metabolic homeostasis and consider how these data speak to the evolutionary origins of obesity.

Evolutionary dynamics of adaptation to starvation selection

Laboratory adaptation in *Drosophila* generally occurs through selection on standing genetic variation, typically resulting in apparent convergent evolution across experimental replicates (Burke 2012; Long et al. 2015; but see Kang et al. 2016). In asexual species, adaptation occurs via a different mechanism, sometimes called “hard” selective sweeps, where beneficial *de-novo* mutations arise then are driven toward fixation (Burke 2012). Hard sweeps in asexual E&R studies tend to be heterogeneous across replicate populations and implicate candidate alleles private to a single replicate (e.g. Tenaillon et al. 2012; reviewed in Long et al. 2015). Here we observe heterogeneous sweep patterns among our evolutionary replicates (S_{A-C}) with large (100-2000 kb) footprints of low heterozygosity that approach fixation. While this may be consistent with a hard sweep model, it is

extremely unlikely that *de-novo* mutations are driving adaptation due to the small population sizes ($\sim 10^3$) and relatively low number of generations in our experiment. While near-fixation of large portions of the genome may also be caused by genetic drift, there was little evidence of large-scale fixation in any of the F populations which were under drift for the same number of generations with roughly equal population sizes. Instead we suspect that differences in experimental design explain many of the differences from other E&R experiments in *Drosophila*. For instance the starvation-selection regime imposes extreme selection pressures ($\sim 85\%$ mortality/generation) which are lethal, analogous to experimental culling or domestication (Rose et al. 1990; Bennett 2003). While a few artificial selection studies in *Drosophila* have also reported fixation, the degree of fixation in these studies is not as pervasive as reported here and generally localized to small numbers of ~ 10 -50kb windows, which is consistent with complete soft sweeps (Turner et al. 2011; Zhou et al. 2011). One study on desiccation-selected *Drosophila* also found evidence for hard selective sweeps, but at a lower frequency than reported here (Kang et al. 2016). A more appropriate comparison may then be made with studies on domestication, such as genomic data from domesticated rabbits which similarly demonstrate large troughs in heterozygosity that are inconsistent across populations/strains (Carneiro et al. 2014). The large sweeps (~ 300 kb) in our dataset are consistent with high selection pressure, as studies in domesticated rice have used the size of selective sweeps to estimate the strength of selection- with large selective sweeps associated with high selection strength (Olsen et al. 2006).

Selection can affect rapid allelic change especially as selection coefficients approach 1, and rapid fixation would allow less time for recombination events to break apart linked

loci, leading to larger sweep sizes. While we do not have genetic data to track allele frequencies over the course of selection, experimental selection for starvation resistance in the S populations and in similar studies have revealed rapid adaptation with evolved responses within as few as 5 generations despite differences in selective strengths ranging from ~85% mortality/generation in the S populations (data unpublished) to ~50% mortality/generation elsewhere (Harshman and Schmid 1998). In nature, *Drosophila* must adapt rapidly to seasonal changes in climate and polymorphisms with large effects on starvation resistance phenotypes have been shown to vary in their frequency by nearly 20% per season (Bergland et al. 2014; Paaby et al. 2014). It is therefore possible that starvation selection in *Drosophila* is unique in that it selects on loci with an evolutionary history of rapid adaptation. Because selection pressures in the laboratory are likely much higher than experienced in the wild, these alleles may be pulled toward fixation rapidly. Rapid adaptation is also consistent with epigenetic inheritance as parental nutritional status may alter chromatin structure in both humans and *Drosophila* (Stöger 2008; Buescher et al. 2013; Öst et al. 2014). However, we have found no evidence for parental effects on starvation resistance or lipid storage in our lines, suggesting a largely genetic response (data not published). The high strength of starvation selection was also observed in studies where reverse evolution of starvation-selected *Drosophila* failed to fully recover ancestral states, suggesting the possibility of fixation and loss of genetic variation during forward evolution (Teotonio and Rose 2000).

The inconsistency in sweeps across S_{A-C} is also different from most E&R experiments in *Drosophila* and may be a consequence of selection acting on multiple adaptive solutions to the same evolutionary problem. This has been observed in experimental selection for

high levels of physical activity in mice, where half of the replicate selected populations have evolved a “mini-muscle” phenotype that confers an increase in oxidative capacity (Garland Jr. et al. 2002; Garland Jr. 2003). Differential selection may be influenced by founder effects as subtle variations in allele frequency in the starting population may promote disparate evolutionary trajectories (Garland Jr. 2003). Here, small allelic differences in the founding populations may have further differentiated during the 70-generation “lead in” to starvation selection when the S populations served as controls for a desiccation selection experiment with mild selection pressures (~20% mortality/generation, Figure 3.1B, Methods). Adaptation by drift or selection during this period may have amplified ancestral allelic differences in the S populations, leading to divergent evolution when severe starvation selection was imposed.

The physiological mechanisms to survive starvation are diverse and may offer many independent targets for selection. For instance, *Drosophila* may adapt to starvation selection by increasing energy reserves, reducing energy consumption rates or increasing the tolerance of organ systems to starvation stress (Rion and Kawecki 2007; Gibbs and Reynolds 2012; Schwasinger-Schmidt et al. 2012). These physiological mechanisms are likely built upon complex genetic networks that may be convergent, but may also function independently. This is supported by studies in iso-female populations of *Drosophila* where these genetic networks may be isolated. Such studies have found that genes underlying energy storage and utilization are independent, as metabolic rate and stored TG correlate poorly across strains (Jumbo-Lucioni et al. 2010). However, the interaction between these networks is important for starvation survival as neither metabolic rate nor stored TG correlated well with starvation resistance in iso-female lines (Hoffmann et al. 2001; Jumbo-

Lucioni et al. 2010). In natural populations and in large outbred evolution experiments, these traits are highly correlative with starvation resistance, suggesting the ability to properly utilize energy stores during starvation is dependent on genetic background and epistasis (Ballard et al. 2008; Schwasinger-Schmidt et al. 2012; Reynolds 2013). The genes controlling the broad physiological mechanisms such as reduction of energy expenditure may also be diverse as multiple adaptations such as lower metabolic rate, reduced physical activity and disrupted sleep cycles have been reported in starvation-selected *Drosophila* (Schwasinger-Schmidt et al. 2012; Reynolds 2013; Masek et al. 2014). This potentially offers more selective targets as some of these phenotypes may be genetically independent (e.g. an allele that disrupts flight muscle may reduce physical activity but have no effect on sleep duration). While increased lipid stores and decreased energy expenditure are consistent adaptations in the S populations (Reynolds 2013; Masek et al. 2014), the genetic basis of these phenotypes may be driven by different mechanisms, which could help explain the variation in allele frequency among S populations.

While highly unlikely, our data are consistent with hard selective sweeps and could suggest beneficial *de-novo* mutations within the dataset. This hypothesis is difficult to address because we lack sequence information from the founding populations. Even when founding populations are sequenced, it is hard to determine if a low frequency variant existed in the starting population due to sampling or sequencing error. The likelihood of a *de-novo* mutation could be higher if any part of the starvation-selection regime inadvertently increased mutagenesis/genomic re-arrangements such as starvation-induced mutagenesis in prokaryotes and yeast (Coyle and Kroll 2008) or diet-induced genomic rearrangements in *Drosophila* (Aldrich and Maggert 2015). The only way to test these

hypotheses is to restart evolution with the intended purpose of resequencing, using recently developed guidelines for increased replication and time-series sampling (Baldwin-Brown et al. 2014; Kofler and Schlotterer 2014).

Experimental selection for starvation resistance alters the frequency of alleles associated with metabolic homeostasis.

Analysis of the candidate genes revealed the potential for many adaptive mechanisms which will require further study. For instance, changes in locomotion and behavior could be affected by candidates such as *foraging* and *couch potato*, which are well-known regulators of these phenotypes (Schmidt et al. 2008; Kent et al. 2009). Furthermore, the S flies are developmentally delayed and have disrupted 20-hydroxyecdysone signaling (Reynolds 2013), which could be due to allelic differences in candidates associated with steroid hormone signaling including *Smtcr*, *Ecdysone-induced protein 75B*, *Nitric oxide synthase*, *ultraspiracle* and *βFTZ-F1* (Hall and Thummel 1998; Tsai et al. 1999; Fortier et al. 2003; Hong and Park 2010; Caceres et al. 2011; Koyama et al. 2014). However, we decided to focus on candidates involved in metabolism because shifts in metabolic homeostasis are a consistent response to starvation selection (Chippindale et al. 1996; Harshman et al. 1999; Gibbs and Reynolds 2012; Schwasinger-Schmidt et al. 2012; Reynolds 2013) and these physiological changes correlated with selection on genetic variants involved in regulating metabolism ($p < 4.1 \times 10^{-8}$, Table 3.1). Furthermore, we found enrichment for signaling pathways controlled by receptor tyrosine kinase (RTK) and G-protein coupled receptors (GPCR) ($p < 1.5 \times 10^{-5}$, $p < 1.2 \times 10^{-3}$, Appendix C Supplementary Gene Ontology Table). In *Drosophila*, insulin-like peptides (Ilp) and adipokinetic hormone (Akh) signal

through receptors of the RTK and GPCR families respectively, to regulate metabolism by coordinating cellular responses to balance systemic nutrient levels. The downstream components of these pathways are interconnected, creating a network that shifts between pro-growth, anabolic processes in response to Ilp secretion or catabolic metabolism and stress-resistance in response to Akh (Figure 3.9). These pathways are remarkably conserved among metazoans and function analogously to insulin and glucagon signaling in mammals (Geminard et al. 2006; Piñero González et al. 2009). Of the many processes implicated in this study we limited our focus to genes associated with these pathways because they were strongly targeted by selection, have well-characterized roles in controlling starvation resistant phenotypes and are highly conserved in mammals- with implications in obesity and its associated diseases.

Alleles of receptors and upstream components of important metabolic pathways are favored targets of starvation selection.

In the S populations the receptors for both insulin and adipokinetic hormone signaling were targeted by selection (candidates hereafter displayed in **boldface**, **InR** and **AkhR**, Figure 3.9). Disruptive mutations in either receptor have profound metabolic consequences, with pleiotropic effects in varying tissues, as ecological factors such as nutrition and stress are decoupled from the intracellular metabolic machinery (Brogiolo et al. 2001; Tatar 2001; Grönke et al. 2007; Bharucha et al. 2008; Kayashima et al. 2013). Despite high levels of conservation across *Drosophila* species, receptors have evolved under relatively low levels of selective constraint compared to other protein families in *Drosophila* (Clark et al. 2007). Relaxed constraints may have allowed intra-species

variation to persist despite evidence of positive selection driving adaptive changes in receptor sequences across species (Schmidt et al. 2000; Guirao-Rico and Aguade 2009). Experimental evidence has shown this may be the case for at least the **InR**, as polymorphisms in natural populations of *D. melanogaster* show clinal patterns of positive selection and associate with variation in fecundity, development time, lipid weight and starvation resistance (Paaby et al. 2010; Paaby et al. 2014). In the S populations we found 71 and 20 loci within **InR** and **AkhR** respectively, which were consistent with selection. Many of these SNPs were found in non-coding regions which have the potential to alter regulation of the receptors themselves, but could also affect remote targets. For **InR** we also found predicted amino acid substitutions His1150Tyr and Asp1192Gly which reside in the second fibronectin type-III domain, an extracellular region which has been associated with Ilp ligand binding (Garza-Garcia et al. 2007; Sajid et al. 2011). We also found a predicted non-synonymous Thr389Asn substitution in the cytoplasmic domain of **AkhR** near the C-terminus. Threonine residues in similar regions of AkhR in *Bombyx mori* are crucial sites for proper AkhR trafficking, with disruption altering receptor internalization and desensitization in response to Akh signals (Huang et al. 2011).

Comparative studies of the insulin pathway across *Drosophila* species have found lower levels of selective constraint and higher sequence diversity in upstream components of the pathway compared to downstream effectors (Alvarez-Ponce et al. 2008). This pattern may help explain why selection in the S populations favored alleles of upstream kinases/phosphatases, phosphodiesterases, G-proteins, phospholipases, perilipins, transcriptional co-activators, adenylyl cyclases and calcium channels (Figure 3.9), while major downstream transcription factors were conserved (*foxo*, *Creb*, *SREBP*, ect.).

Furthermore, proteins with high degrees of known connectivity such as Akt and Tor, were not targeted by selection in the S populations. These proteins may be constrained by selection acting antagonistically on different pathways or could be a function of low diversity due to an evolutionary history of positive selection on highly interconnected nodes (Alvarez-Ponce et al. 2008).

Ligands of the Insulin and Adipokinetic Hormone signaling pathways are largely conserved with the exception of Ilp6.

Ligands of the neuropeptide hormone family including Ilps and Akh are highly evolutionarily conserved due to strong stabilizing selection across the *Drosophila* phylogeny (Wegener and Gorbashov 2008; Guirao-Rico and Aguade 2011). Consistent with these findings, we did not find evidence for selection in any ligand of these pathways, with the notable exception of **Ilp6**, the homolog of insulin-like growth factor and the only one of 8 Ilps primarily expressed in the fat body (Kannan and Fridell 2013). **Ilp6** is released from the fat body and acts hormonally to coordinate the mobilization of energy stores when nutrients are low during starvation or developmental periods such as metamorphosis (Okamoto et al. 2009; Slaidina et al. 2009). In the S populations loci across **Ilp6** were found in synonymous or non-coding regions, which could alter regulatory mechanisms of **Ilp6** but may impact remote targets. In *Drosophila*, **Ilp6** is known to be under transcriptional control of Foxo, which is activated in response to Akh signaling in low nutrient conditions (Okamoto et al. 2009). If selected loci were to disrupt such a regulatory pathway it could be an adaptive response to block lipid mobilization during starvation, as **Ilp6** is known to promote lipolysis through the oenocytes and inhibit systemic insulin signaling in the IPCs

(Chatterjee et al. 2014). Alleles that lower **Ilp6** expression would then promote an anabolic state even under starvation conditions. The tradeoff between lipid storage and reproduction in the S populations is also consistent with **Ilp6** misexpression, as **Ilp6** mutants have small ovaries due to an inability to mobilize energy stores from the fat body during metamorphosis (Okamoto et al. 2009; Reynolds 2013).

Selection on alleles associated with lipolysis may alter the mobilization of lipids in response to fasting signals.

Lipid mobilization in insects is stimulated by Akh and octopamine signals which are homologous to glucagon and noradrenaline-stimulated lipolysis in mammalian adipocytes (Arrese and Soulages 2010). These hormones are released in response to starvation and increase intracellular levels of secondary messengers cAMP and Ca^{2+} in peripheral tissues through G-protein mediated cascades. High levels of intracellular cAMP and Ca^{2+} are critical in activating lipases associated with lipid droplets and promoting catabolic gene expression through **Crtc**/Creb and Foxo (Chino et al. 1989; Lum and Chino 1990; Patel et al. 2005; Arrese et al. 2008; Arrese and Soulages 2010; Wang et al. 2011; Yang et al. 2013). Many members of the lipolytic pathway were associated with adaptation within the S populations including receptors (**AkhR**, **Oamb**, **Oct β 2R** and **Oct β 3R**), the G-protein α subunit (**G α q**), adenylyl cyclases (**Ac76E**, **Ac13E**, **rut** and **CG43373**), phosphodiesterases (**Pde1c,6,8,9,11** and **dnc**), protein kinase A-catalytic subunit (**Pka-C3**), lipid storage droplet 1 (**Lsd-1**), phospholipase C (**Plc21c**) and plasma membrane Ca^{2+} channel (**Olf186-F**; Figure 3.9).

Because the S populations have evolved physiologies to store and resist mobilization of lipids, it is tempting to view the large number of candidates in these pathways as part of an adaptive response to attenuate lipolysis in response to starvation-

induced signals. While this remains to be tested, one particular area of interest is in the genes maintaining cAMP levels as they were over-represented in the S populations ($p < 3.6 \times 10^{-4}$, Appendix C Supplemental Gene Ontology Table) and cAMP production rates are correlated with the rate of lipolysis and influence adipocyte size in mammals (Arner et al. 1979; Mowers et al. 2013). Intracellular cAMP is synthesized from ATP through adenylyl cyclases (ACs) and converted to AMP through phosphodiesterases (PDEs). In the S populations, selection targeted alleles across 4 AC and 6 PDE genes which are distributed across the genome and thus likely independent targets of selection and not linkage artifacts of gene clusters. Natural polymorphisms and mutations in many of these enzymes are associated with major metabolic consequences in *Drosophila* and mammals (Tong et al. 2007; Mattila et al. 2009; Wang et al. 2009; Jumbo-Lucioni et al. 2010; Basile et al. 2014; Maurice et al. 2014; Knigge et al. 2015; Locke et al. 2015).

While the effects of PDEs on lipolysis in *Drosophila* are poorly characterized, it has long been known that chemical inhibition of PDEs increases lipid mobilization in insects (Spencer and Candy 1976). Furthermore, recent studies in *Drosophila* have found that PDEs may affect metabolism by influencing food preference, which is altered in the S populations (Masek et al. 2014; Zhang et al. 2015). While allelic variants of the PDEs in the S populations were largely found in non-coding regions, post-translational regulation of PDEs can be heavily influenced by splice variants in mammals, and different isoforms exist in *Drosophila* PDEs (Sonnenburg et al. 1995; Day et al. 2005; Lu and Sewer 2015). Variants that promote dysregulation of PDEs could impact lipolysis in the S populations and help explain how lipid droplets within the fat body are ~115% larger in volume in a fed state (Hardy et al. 2015). Furthermore, in mammals PDE deregulation during the onset of type-II

diabetes may promote the lipolytic release of free fatty acids into the blood stream, leading to lipotoxicity in peripheral tissues (Choi et al. 2006; Morigny et al. 2015). Despite higher total body fat, the S flies resist ectopic lipid storage in the heart, which could also be a result of decreased lipolysis of TG stores in the fat body (Hardy et al. 2015). These findings now correlate with selection on several PDEs and genes involved in cAMP metabolism which warrants further investigation of their role in lipolysis in the fat body.

Selection on genes which relay environmental signals to Tor may decouple metabolism from nutrient availability.

Target of Rapamycin (Tor) is responsible for integrating nutritional and stress signals in the cell and coordinating a metabolic response to promote cell growth in high energy, low-stress cellular environments (Pan et al. 2004). It does this by activating many downstream targets, including proteins involved in translation, transcription factors with anabolic gene targets and by negatively regulating autophagy (Pan et al. 2004; Jin et al. 2015). In the S populations many of the pathways that relay signals from the cellular environment to Tor were targeted by selection, including candidates involved in sensing dietary amino acids (**happyhour**) and sugars (**InR**, **chico**) as well as cellular energy (**AMPK- γ subunit**) and generalized stress signals (**sestrin**; Bryk et al., 2010; Edgar, 2006; Hardie et al., 2012; Johnson et al., 2010; Kim and Neufeld, 2015; Kim and Lee, 2015; Lee et al., 2013, 2012, 2010; Figure 9). Interestingly, many of Tor's downstream effectors including S6K, 4E-BP, TIF-1A, SREBP and Myc were not targeted by selection with the exception of candidate **Atg1** which is repressed by Tor and critical in initiating starvation-induced autophagy (Scott et al. 2004; Figure 9).

Allelic changes to genes in pathways responsible for relaying nutritional and stress signals may be an adaptive response to allow S flies to maintain anabolic activity in the face of stressful, starvation conditions. For example, low cellular energy (by a low ATP/AMP ratio) activates AMPK through its regulatory subunit (candidate **SNF4A γ**) to inhibit Tor activity (Gwinn et al. 2008; Kim and Lee 2015; Figure 9). AMPK can also be activated by candidate **sestrin**, a protein that accumulates in response to cellular stress and is under transcriptional control of Foxo through the Akh pathway (Lee et al. 2010; Bednářová et al. 2015). Starvation may then activate AMPK through the Akh pathway to block Tor by increasing **sestrin** expression through Foxo and stimulating **AMPK- γ** by altering ATP/AMP levels by activating AC and PDE. If allelic differences in stress response genes such as **sestrin** and **AMPK- γ** are less efficient in repressing the activity of metabolic regulators such as Tor, they could shift metabolic homeostasis in favor of anabolic processes despite nutrient deprivation and high stress. In the S populations this could contribute to a genetic predisposition towards obesity and help explain how they maintain high adult body fat remains high despite consuming fewer calories than the F controls when fed *ad libitum* (Masek et al. 2014; Hardy et al. 2015).

Evolutionary Implications

Theories on the evolutionary origins of obesity began with the proposition of the 'Thrifty Gene Hypothesis' (TGH), which postulates that genes that are efficient in storing and retaining energy are selected for during periods of famine (Neel 1962). Critics have argued that famines severe enough to drive evolution are relatively rare events in human history and cite the lack of candidate obesity genes under selection as weaknesses of the theory (Speakman 2008; Stöger 2008; Genné-Bacon 2014). Clearly our experimental

design supports the TGH as a generalized model given the extensive evolutionary history of severe famine which has led to adaptive 'thrifty' physiologies (i.e. low metabolism, higher energy storage) in the S populations. Here we provide further support for the TGH as we report a wide range of genetic loci with widely divergent allelic frequencies due to the selective treatment. Whether the TGH contributes to the current obesity epidemic in humans is still up for debate, but its effects here are pervasive and may speak more generally to the evolutionary forces controlling obesity.

3.5 Methods

Evolutionary history of the starvation-selected lines

The starvation-selected lines were derived from the controls of a desiccation-selection experiment which began in 1999 as previously described (Gefen and Gibbs 2009) and diagramed in Figure 3.1B. Briefly, the founders for the desiccation-selection experiment were derived from ~400 adult female *Drosophila melanogaster* that were collected from the wild in Terhune New Jersey in 1998. These animals were acclimated to lab conditions for one year, then split into three large cohorts (“D”, “SC” and “FC”), each with 3 replicates (“A”, “B” and “C”) for a total of 9 populations (Figure 3.1B, grey phylogeny). D_{A-C} were selected for desiccation tolerance, with 4-day-old adults from each generation being deprived of food and water and stressed with artificial desiccant until 80-90% of the population had died. Survivors were re-fed, bred and used as founders for the next generation. Because the desiccation treatment also removes food, D_{A-C} were moderately selected for starvation resistance. To control for the effects of starvation, SC_{A-C} were starved during the selection phase of each generation, given non-caloric agar to provide water, but otherwise handled in parallel with D_{A-C}. FC_{A-C} was ostensibly unselected, a handling control given *ad libitum* food and water each generation.

The starvation-selection experiment studied here started in 2006, 70 generations after the start of the desiccation-selection experiment. The starvation-selected populations (hereafter “S_{A-C}”) were derived from SC_{A-C} as previously described (Reynolds 2013; Masek et al. 2014; Hardy et al. 2015). Each generation ~10,000 S adults were raised for 4 days, then food was replaced with non-caloric agar until 80-90% of the population had died. Survivors were allowed to breed and served as founders for the next generation. At the

same time, subpopulations were derived from FC_{A-C} of the desiccation-selection experiment and maintained in parallel with S_{A-C}. These lines were ostensibly unselected, with ~2,000 flies given unrestricted access to food and water each generation (Fed-controls, hereafter “F”; Figure 3.1B, black phylogeny).

Sample Preparation

Flies were removed from selection for one generation following the 83rd generation of starvation selection to control for parental effects. Pooled samples of 100, 4-day-old adult females were then collected from all 6 populations (F_{A-C}, S_{A-C}). Pooled samples were homogenized using glass tissue homogenizers in a proprietary buffer (ATL) in accordance with the DNeasy[®] Blood and Tissue DNA Extraction Kit (Qiagen, Valencia CA). We followed the manufacturer's protocol for purification of total DNA from animal tissues including the optional RNase step. DNA purity and concentration were calculated using a NanoDrop[®] ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE.).

Library Preparation and Sequencing

Purified samples were shipped to the University of Utah Health Science Center Genomics Core Facility to generate paired-end libraries with 350-bp mean inserts using the TruSeq[®] DNA PCR-Free Preparation Kit (Illumina[®], San Diego CA.). Multiplexed samples were sequenced using an Illumina HiSeq[™] sequencer with 125-cycle paired-end sequencing using version-4 chemistry.

Mapping and Variant Discovery

Raw reads were aligned to the *Drosophila melanogaster* genome (Flybase, r6.06) using the Burrows-Wheeler Aligner program (BWA, version 0.7.12) with default settings. Unmapped, low quality (<20) and singleton reads were removed from the Binary Alignment Map (BAM) file, which was then sorted by genomic coordinate using SAMtools (version 1.1). Duplicate reads were removed and the resulting de-duplicated BAM files were merged using Picard (version 1.123). Reads were locally realigned around putative indels using tools in the Genome Analysis Toolkit (GATK, version 3.3) from the Broad Institute. Variants were identified using the Unified Genotyper tool from GATK and annotated with SnpEff (version 4.1) using a custom database built through SnpEff, based on the latest Gene Transfer Format (GTF, r6.06) release from FlyBase (Attrill et al. 2016).

Filtering for Quality Control and Sampling Error

A series of quality control measures were performed using the VariantFiltration tool from GATK. To start, SNPs within 5 nucleotides of a putative insertion or deletion (indel) were discarded to control for mapping errors that occur frequently near indels. In addition we filtered closely clustered SNPs (3 SNPs within a window of 10 nucleotides), SNPs with poor phred-based quality scores (QUAL < 30), high strand bias (FS > 60) or greater than four mapping quality scores of zero across all samples (MQ > 4). Variant Call Format (VCF) files were converted into a customized SNP table with reference and alternate allele counts for each population and ordered by genomic position for chromosomes X, 2L, 2R, 3L and 3R using command line text editors. During this step SNPs with less than 30x coverage across all 6 populations or with more than 1 alternate allele were discarded. Using custom R

scripts (R Core Team 2015), SNPs with a minor allele frequency of less than 0.05 across all 6 populations were filtered as well.

After quality control filters were applied, the SNP table contained 1,046,373 SNPs with 72.6 ± 5.9 (S.E.M.) fold coverage across all 6 populations. To support that our SNPs were largely natural polymorphisms and not due to misalignments, we compared them to those available in the Drosophila Genetic Resource Panel (DGRP Mackay et al. 2012). To do this we downloaded the Variant Call Format (VCF) file for the DGRP Freeze 2.0 calls from dgrp2.gnets.ncsu.edu/data.html. Genomic location was extracted from the `dgrp2.vcf` file using custom command line text editors to generate a file with the chromosome and position of each SNP. The genomic positions of the DGRP calls and our set of SNPs were based on different FlyBase genome assemblies, resulting in discordant genomic coordinates. To match our coordinates we used the Drosophila Sequence Coordinates Converter from FlyBase (Attrill et al. 2016) to switch our SNPs from the version 6 assembly to the version 5 assembly. The converted positions were uploaded into R and compared to the DGRP SNP locations. In total we found 94.6% overlap between our SNPs and naturally occurring polymorphisms in the DGRP lines (data not shown).

In order to filter SNPs that could be explained by sampling error we used a scaled Chi-Squared test (Huang et al. 2012), which was applied independently to each replicate pair (ie. FA compared to SA; Appendix B Supplementary Code). To correct for multiple comparisons we used a Bonferonni correction with a 0.01 adjusted p-value threshold. This step filtered ~88% of the SNPs with 120,825, 115,000 and 168,100 SNPs remaining for replicates A, B and C respectively.

Principal Component Analysis and Pearson Product-Moment Correlation

We used the Principal Component Analysis (`prcomp`) function of the *stats* package (version 3.1.3) in R to visualize differences in reference allele frequency across populations. In R, we plotted the pairwise coordinates of the first 3 components which explained 88% of the variation (Appendix A Table S3.1). Also using the *stats* package in R we performed the Test for Association/Correlation Between Paired Samples (`cor.test`) to calculate the Pearson Product-Moment Correlation Coefficient (r) for pairwise associations of reference allele frequencies between populations. P-values for all correlations were $< 2.0 \times 10^{-16}$ (data not shown).

Starvation Resistance

Flies were removed from selection for one generation to control for parental effects. The progeny were aged to 4 days post-eclosion, briefly anesthetized with CO₂, then separated into vials containing non-caloric 1% agar. Each vial contained either 5 males or females from the 3 selected populations (SA, SB or SC), with a total of 10 vials per sex, resulting in a total of 100 flies (50 males, 50 females) per population. All vials were maintained on a 24-hour light cycle at 25°C and scored for mortality every 8 hours until the completion of the experiment. Every 3 days flies were manually transferred (without anesthetic) to fresh vials to replenish water resources. Data were split for each sex and processed in R, using a one-way ANOVA with population as the categorical factor for each sex followed by a Tukey *post-hoc* test.

Heterozygosity

Heterozygosity for each SNP was calculated as $2pq$ with the alternate alleles divided by total coverage for that SNP, per population. Custom functions in R were used to calculate the average heterozygosity of SNPs within 100kb windows with a step size of 2kb across the genome. Mean block heterozygosity was calculated from the total number of 100kb windows for each population, with a one-way ANOVA and Tukey's *post-hoc* test used to find statistical differences. We calculated the variance in the mean heterozygosity for all 100kb blocks within each population and used the "F Test to Compare Two Variances" (`var.test`) function in the *stats* package in R to test for pairwise differences between populations. We found contiguous blocks of low heterozygosity by locating overlapping 100kb blocks whose mean heterozygosity was less than 0.05 using the Intervals (version 0.15.0) package in R. Contiguous blocks were analyzed for count, size and genomic location. Overlapping regions of contiguous blocks from populations SA, SB and SC were found and the coordinates of these overlaps were used to find genes using a custom gene database, built from the r6.06 FlyBase release.

Human Orthologs

We uploaded our list of 1,453 candidate genes into FlyMine v41.0 to search for gene ontology enrichments, pathway enrichments, expression patterns and orthologs. Using the 'Orthologs Widget' we found 1,041 of our genes had an ortholog in *Homo sapiens*. In total we found 2,846 human orthologs due to genetic redundancy in higher metazoans. This set of genes was uploaded to Enrichr, an online mammalian gene-list enrichment

analysis tool (Chen et al. 2013). We analyzed our gene-set for enriched mammalian disease terms against Enrichr's Online Mendelian Inheritance in Man (OMIM) Disease gene-set.

A

B

Figure 3.1 Selection regime, phylogeny and evolutionary history of the selected populations. (A) Each generation the starvation-selected populations S_{A-C} were starved until 80-90% had died. The survivors were used as founders for the subsequent generation. At the same time the fed control populations F_{A-C} were handled in parallel and fed *ad libitum*. The visible differences between F_{A-C} and S_{A-C} as 4-5 day old adults demonstrate some of the evolved characteristics. (B) Detailed phylogeny and evolutionary history of the starvation-selected lines. Axis to the right displays the number of generations and year. Black lines represent the starvation-selection experiment studied here. To date, the starvation-selection experiment has been running for over 100 generations, however sequence data was collected at generation 83.

Figure 3.2 Genetic heterogeneity in the starvation-selected replicates. (A-C) Principal Component Analysis (PCA) plots of the first 3 components, which explain ~88% of the variation in reference allele frequency between the populations. Dark grey circles represent populations S_{A-C} while the light grey circles represent F_{A-C} . F_{A-C} cluster together and are separated from the S populations. The S_A population appears to cluster independently from S_{B-C} . (D) Pairwise Pearson Product Moment Correlation Analysis of all 6 populations. Darker squares represent a higher degree of correlation in reference allele frequency.

Figure 3.3 Differences in starvation resistance between the starvation-selected populations match patterns of genetic heterogeneity. The S_A population is significantly better at surviving starvation than the S_B and S_C populations for both (A) Females and (B) Males. Different letters signify statistically different groups where $p < 0.05$; Tukey Posthoc; ANOVA; $N = 47-50$.

Figure 3.4 Genome-wide heterozygosity. (A-C) Genome-wide sliding window heterozygosity plots (100kb window, with 2kb steps). S_{A-C} (red) display many regional declines in heterozygosity, while F_{A-C} (black) heterozygosity remains stable. This results in (D) lower mean heterozygosity per 100kb block and (E) increased levels of variance in the selected lines. Different letters signify statistically different groups where $p < 0.05$. See methods for statistical tests.

Figure 3.5 Selective sweeps are large and inconsistent in the starvation-selected populations
 (A) S_{A-C} have many extended regions of low heterozygosity approaching fixation ($2pq < 0.05$), (B) which average ~300kb in size but range from ~100 to 2000kb. (C) The large contiguous blocks of heterozygosity are inconsistent across replicates. On the “All” horizontal axis are the 4 regions of overlap across the S populations. The regions of low heterozygosity are not to scale; they were made large to visualize the approximate region.

Figure 3.6 Filtering for genetic drift. (A) Effective population size was estimated from the data using Equation 2, plotted here as a function of the starting allele frequency. (B) Posterior density distribution of post-drift allele frequency for each starting allele frequency in $\{0.01, 0.02 \dots 0.50\}$. These distribution were obtained using Kimura's diffusion equation. (C) Histogram, showing the 1.0×10^7 values of absolute difference in allele frequency obtained from simulating 2 populations under drift. The 99.999% quantile of each distribution became the Drift Threshold. (D) Relationship between the starting allele frequency and the Drift Threshold for autosomes (black) and the X chromosome (red).

Figure 3.7 Candidate loci (A-C) Absolute difference in allele frequency between the replicate F-S pairs. Red points indicate SNPs whose absolute difference in allele frequency is greater than the Drift Threshold, making them consistent with selection. The loci in black could not be distinguished from drift.

Figure 3.8 Mapping candidate loci to genetic features and biological processes. (A) The S populations had nearly identical distribution of SNPs in different genomic elements. (B) Selection targeted dissimilar loci across S replicates, but converged on more similar (C) genes and even more similar (D) biological processes.

CHAPTER 4

FUNCTIONAL GENOMIC ANALYSIS OF DIFFERENTIAL GENE EXPRESSION IN THE FAT BODY DURING PUPARIATION IN STARVATION-SELECTED *DROSOPHILA MELANOGASTER*.

4.1 Abstract

During development, holometabolous insects do not feed for an extended period, beginning near the end of the final larval instar and persisting through the beginning of adulthood. In preparation, larvae feed continuously and amass large amounts of lipids and storage proteins, which are stored in the fat body. During pupariation the larval fat body is remodeled in response to the steroid hormone 20-hydroxyecdysone (20E). This results in the dissociation of the larval fat body into individual cells. Lipids within these cells are catabolized to provide energy for the other developing tissues throughout metamorphosis. In *Drosophila melanogaster* some larval fat cells persist into the first couple days of adult life. These cells provide an important source of energy to the adult fly, which may be allocated towards reproduction or used for processes such as starvation resistance. Laboratory selection for starvation resistance in *D. melanogaster* causes the selected larva to be developmentally delayed. This delay increases their larval feeding period and allows for the accumulation of excess lipids. These larval-derived lipids are carried by the larval fat body into adulthood where they play a critical role in adult starvation resistance. Despite the importance of these events in driving starvation resistance, there have been few studies on the mechanistic basis of the delay or the physiology of the larval fat body

during development. We studied populations of *D. melanogaster* that had been laboratory selected for starvation resistance for over 70 generations. Selection has led to a ~24 hour delay in larval development. We previously demonstrated that this delay correlates with a ~24 hour delay in the expression of a 20E-inducible gene, *E74A*. This led us to hypothesize that selection altered the timing of 20E signaling. If this hypothesis is correct, we predicted that the expression profiles of 20-inducible genes during and after the onset of pupariation would be similar between the selected populations and their unselected controls. To test this, we sequenced genomic RNA from the fat bodies of F and S larvae, sampled during and after the initiation of pupariation. In support of our hypothesis, a majority of differentially expressed genes were altered in response to the developmental timepoint. However, we also found many genes which were differentially expressed in response to selection. This set was enriched for upregulation of genes associated with the proteasome, spliceosome and mitochondrial translation, as well as the downregulation of many catabolic genes. These results suggest that 20E signaling is altered in the fat body in response to starvation selection.

4.2 Introduction

The life cycle of holometabolous insects can be broadly divided into the egg, larval, pupal and adult stages. Each stage is separated by dynamic developmental transitions that profoundly alter the morphological and physiological status of the animal. Throughout the entire life cycle, energy must be acquired and utilized to drive development, growth and ultimately fuel reproduction. This is particularly challenging for holometabolous insects because their ability to feed changes during each developmental stage. For example, they are unable to feed during a long period of development, which spans portions of the larval, pupal and adult stages. In *Drosophila melanogaster*, this window begins before the onset of pupariation, near the end of the 3rd larval instar, and persists until several hours after metamorphosis, a period spanning ~4-5 days (Tyler 2000; Aguila et al. 2007).

Insects are able to meet the high energetic demand during the non-feeding window by accumulating energetic reserves during the larval stages. The energy derived from larval feeding is critical in fueling the complete reorganization of the animal during metamorphosis and also constitutes a significant portion of the adult energy reserve (Aguila et al. 2007; Aguila et al. 2013). In *D. melanogaster*, much of the larval-derived energy is stored in the form of lipids in the larval fat body. During metamorphosis, lipids accumulated during larval development are catabolized, fueling greater than 80% of total metabolism (Merkey et al. 2011). Larval-derived lipids are additionally carried into the adult fly, where they play an important role in adult starvation resistance and fecundity (Aguila et al. 2013).

The physiology of the larval fat body changes drastically throughout the non-feeding developmental window. This begins at the onset of pupariation, when hormonal cues

initiate a transcriptional cascade that ultimately drives the animal to cease feeding and find a suitable site for metamorphosis. Commitment to this developmental transition is largely driven by the synthesis and release of the steroid hormone ecdysone from the prothoracic gland (PG) in the ring gland (Andersen et al. 2013). Once secreted, ecdysone enters peripheral tissues where it is converted into its more biologically active form, 20-hydroxyecdysone (20E). This is accomplished through the enzymatic products of cytochrome P450 genes such as *shade* (Petryk et al. 2003). This leads to a late-larval pulse of 20E that initiates pupariation. 20E elicits tissue-specific responses which can vary between differentiation and growth, remodeling or programmed cell death (Yin and Thummel 2005; Yamanaka et al. 2013).

The larval fat body is remodeled in response to the late-larval pulse of 20E, leading it to dissociate into individual cells. This is controlled in part through the 20E-induced expression of genes involved in the digestion of the extracellular matrix (Bond et al. 2011). Throughout metamorphosis the number of larval fat cells declines at a slow rate, but some larval fat cells persist into the first few days of adult life (Butterworth et al. 1988). These cells eventually undergo programmed cell death and provide energy for the young adult fly (Aguila et al. 2007). This source of energy is critical for the young adult fly, which continues to develop, despite not feeding for ~8 hours after eclosion (Aguila et al. 2007; references therein). If nutrients are scarce during this period, the energy derived from the larval fat body can be used for adult starvation resistance (Aguila et al. 2007). Otherwise the lipid resources are heavily allocated towards reproduction (Aguila et al. 2013).

When populations of *D. melanogaster* are experimentally evolved to be starvation resistant, they commonly adapt by delaying larval development (Chippindale et al. 1996;

Harshman et al. 1999; Reynolds 2013). This delay provides a longer larval feeding period, during which starvation-selected larvae amass high levels of lipids within the larval fat body. These lipids are carried into adulthood and invested into adult starvation resistance (Chippindale et al. 1996; Harshman et al. 1999; Reynolds 2013). Despite its importance in driving adult starvation resistance, the mechanistic basis of the developmental delay and the physiology of the larval fat body are poorly studied in starvation-selected populations of *D. melanogaster*.

The work described here is part of a broader project to understand (1) if and how 20E signaling is altered in response to starvation-selection, and (2) how this impacts the physiology of the larval fat body. We study these questions in populations of *D. melanogaster* that have been selected for starvation resistance for over 70 generations. In response to selection, the starvation-selected populations (hereafter “S” populations) have evolved many unique physiologies, including a significant ~24 hour delay in larval development compared to their unselected fed controls (hereafter “F” populations; Reynolds 2013). Our preliminary experiments have found that the delay in larval development correlates with a ~24 hour delay in the expression of a key 20E target gene, *E74A* (Reynolds, 2013). *E74A* is upregulated in response to 20E approximately 6-10 hours prior to pupariation in both the F populations and wild-type laboratory strains of *D. melanogaster*, (*w1118*; Beckstead et al. 2005; F populations; Reynolds 2013). Despite having delayed expression, *E74A* is still induced ~6-10 hours prior to pupariation in the S populations (Reynolds, 2013). These data suggest that selection has altered the timing of the late-larval 20E pulse, which we hypothesize gives the animal sufficient time to feed and accumulate lipids. If this is the case, then I predict that the major patterns of 20E-induced

gene expression will be similar in both the F and S populations during the late-larval 20E pulse.

We tested this hypothesis by staging animals both at pupariation and mid-way through their exposure to the late-larval 20E pulse. From these time points we isolated and resequenced RNA from the larval fat bodies to observe genome-wide changes in gene expression. As predicted, we found that a majority of 20E-induced genes (~1,788) had similar patterns of expression between the F and S populations. However, we also found a subset of 645 genes whose expression pattern during this developmental window was altered in response to selection. Further analysis found that selection led to the upregulation of genes associated with the proteasome, spliceosome and mitochondrial translation, along with the downregulation of genes associated with catabolism. These data suggest that starvation selection altered the tissue-specific response of the larval fat body to 20E signaling.

4.3 Methods

Sample Preparation

For a detailed description of the evolutionary history of the F and S populations please see the methods section in Chapter 3. To begin preparation for RNA collection, flies were removed from selection for 1 generation to control for parental effects. Then approximately 100-200 F1 adult flies from each population were housed in cages and given molasses egg caps with yeast paste. Every 12 hours egg caps were removed from the cages and 100 1st instar larvae were transferred into vials containing standard media with the addition of 0.05% bromophenol blue. The addition of the dye turns the media blue, which is part of a well-established protocol to approximate the timing of pupariation (Andres and Thummel 1994). Briefly, as larvae feed throughout the 3rd instar, the dye in the food can be visualized through the gut. As the animals stop feeding (~10-20 hours prior to pupariation), the gut gradually clears such that animals with a clear gut are 1-6 hours from pupariation (Andres and Thummel 1994). This physiological stage is routinely used to select animals that have been exposed to the late-larval 20E pulse for ~4 hours. Several hours later there is a brief developmental window just after puparium formation has begun called the white prepupa stage.

To study how gene expression differed between F_{A-C} and S_{A-C} in response to the late-larval ecdysone pulse, we collected 2 samples of 3rd instar larvae with clear guts and 2 samples of white prepupae from each population for a total of 24 samples (Figure 4.1). Each sample consisted of 15-25 dissected fat bodies in DPBS, which were pooled into 150µL of TRIzol® Reagent (Invitrogen Corp, Carlsbad, CA). Extreme care was taken to remove the tightly associated testes and imaginal discs from the preparation. To isolate

RNA, we used the Direct-zol™ RNA Mini Prep Protocol (Zymo Research Corporation, Irvine, CA) under the manufacturers guidelines. RNA quantity and quality were assessed using the Experion™ Automated Electrophoresis System (Bio-Rad Laboratories, Inc, Hercules, CA), with samples prepared using the Experion™ RNA StdSens Analysis Kit (Bio-Rad Laboratories, Inc, Hercules, CA). Each sample was diluted in nuclease free water to 25 ng/μL and sent to the Genomics Center in the Huntsman Cancer Institute at the University of Utah for library preparation and sequencing.

Library Preparation and Sequencing

After quality control, libraries were prepared for each sample using the TruSeq® Stranded Total RNA Sample Prep with Ribo-Zero rRNA Removal (Illumina Inc, San Diego, CA). The protocol did not require a strict size selection, however after adjusting fragmentation time, mean fragments were ~300bp in length. Our experimental design included 2 replicates for each population (F_{A-C} and S_{A-C}) at each developmental timepoint (3IN and WPP) for a total of 24 unique libraries. These replicates were split into 2 groups, which were independently multiplexed and spread onto 2 separate lanes on the flowcell. We then performed a 101-cycle paired-end run with an Illumina HiSeq™ Sequencing System using version 4 chemistry, obtaining nearly 3.50×10^8 reads with an average of 1.46×10^7 reads per library.

Alignment, Feature Counting and Differential Expression

Genome sequences, annotations and indices were downloaded from the *Drosophila melanogaster* dm6 build from UCSC as part of the Illumina iGenomes collection. Raw reads

were aligned to the genome using tools from the Tuxedo Suite (TopHat v2.1.0, Bowtie2 v2.2.6). To align reads to the *Drosophila melanogaster* reference genome, we used TopHat with gene annotations provided from the iGenomes collection using options to filter reads with multiple alignments (max-multihits = 1) or without a successfully aligned paired read (no-mixed). Because our average insert size was ~300bp and we sequenced 100bp from each end we set the average distance between paired end reads to 100bp (mate-inner-dist = 100). Finally, because we used a stranded Illumina TruSeq Kit for library preparation we also implemented the fr-firststrand option.

For each library TopHat generates an alignment file of accepted hits. Reads in these files were sorted by name using SAMtools (version 1.1) to order paired reads together. Sorted alignment files were run through HTSeq (version 0.6.1p2) using the htseq-count function to map reads to genomic features. Specifically, we mapped reads with an alignment quality >20 (minaqual = 20) to exons from the annotation file (genes.gtf) provided in the iGenomes collection. We used the intersection-nonempty mode as a slightly less conservative approach to aligning features and set strandedness to reverse based on our library preparation. Htseq-count assigns each successfully mapped read to a parent gene id, providing a finalized list with read counts per gene for each individual sample.

We developed custom Unix-based command line scripts to concatenate these read count files into a single 16,727 x 24 matrix (X_{ij}). Each index of the matrix contained an integer, representing the read count for each gene (i), corresponding to 1 of our 24 total samples (j). This data table was loaded into R and formatted for integration with DESeq2 for differential expression analysis.

Differential Expression Analysis

For differential expression analysis, we used DESeq2 in R (Love et al. 2014; R Core Team 2015). We implemented a multi-factor design, with selection and developmental stage as the main effects, along with a selection-by-developmental stage interaction term. Levels of selection were “F” for the Fed control populations of “S” for the Starvation selected lines. Levels of the developmental stage term were either “3IN” for RNA samples collected from 3rd instar larva or “WPP” for those collected at the white prepupa timepoint. The model was run through DESeq2 and results were parsed into 3 tables containing genes that were significant for the main effect of selection, development or the interaction term respectively. To perform a *post-hoc* analysis on genes with a significant interaction term, we re-ran DESeq with 1 effect, “Group” with levels of “F3IN”, “FWPP”, “S3IN” and “SWPP”. We filtered the resulting output table for only genes which had a significant interaction effect from the original model. These tables were written out of R into plain text files for enrichment analysis.

Enrichment Analysis

Enrichment analysis for each gene list was performed using FlyMine (Lyne et al. 2007). Gene lists were uploaded and submitted to FlyMine which returns “widgets” with information on enrichment for gene ontology terms, pathways and protein domain categories within the gene list. Gene ontology categories were further optimized to reduce hierarchical clustering using GO-module (Yang et al. 2011). In a few instances, the widget for physical interaction network demonstrated a large degree of physical interactions

within the gene list. These networks were opened in esyN (www.esyn.org), which was used to determine network parameters and export the network image.

Principal Component Analysis and Pearson Product Moment Correlation

The raw count table was imported into R and read counts were normalized by library size. The Principal Component Analysis (PCA) was performed using the *prcomp* function in the stats package in R. The first 2 principal components explained ~96% of the variation in gene expression between samples and were plotted using customized scripts in R. The Pearson Product Moment Correlation Coefficient was calculated using the *pr.comp* function in the stats package in R. Custom scripts were written to perform pairwise correlations. The mean correlation for each major group was calculated in R and differences in the mean were determined with an ANOVA and Tukey *post hoc* test in R.

4.4 Results

Starvation-selection alters genome-wide patterns of gene expression within the fat body in response to pupariation.

The overarching goal of this study is to understand if and how starvation selection alters gene expression throughout pupariation. Therefore we sampled genomic RNA from the F and S populations at two developmental timepoints- during and after the onset of pupariation. This generated 4 major “groups”, the Fed Control 3rd Instar (hereafter “F 3IN”), the Starvation-selected 3rd Instar (hereafter “S 3IN”), the Fed Control White Prepupa (“F WPP”) and the Starvation-selected White Prepupa (hereafter “S WPP”). Each group was defined by 4 factors; the selection treatment (F | S), developmental timepoint (3IN | WPP), the evolutionary replicate population of origin (A | B | C) and the biological replicate (1 | 2)(see Figure 4.1 for an overview of the experimental design). In total this design led to 24 independent RNA libraries- or hereafter “samples”- with 6 samples in each of the 4 major groups.

Before performing differential expression analysis to look for gene-level differences between groups, we performed a Principal Component Analysis (PCA) to visualize the relationships in genome-wide expression patterns between all 24 samples. We plotted the first two principal components, which explained a combined ~96% of the variation in gene expression across samples (Figure 4.2). We first examined the patterns of gene expression across the 3IN groups. We observed that the expression patterns between F 3IN and S 3IN were fairly similar, but slightly separated by selection treatment (Figure 4.2; F 3IN: light gray; S 3IN: light red). The subtle differences between these groups were largely overshadowed by the high degree of separation between the 3IN and WPP groups (Figure

4.2; F WPP: Dark gray; S WPP: Dark red). Interestingly, samples in the S WPP group were highly variable, especially compared to the tight clustering of samples within F WPP (Figure 4.2). Most of the variation within the S WPP group was due to differences between the replicate populations, as the two S_A WPP biological replicates were more closely associated with samples from the F WPP group than they were to the S_{B-C} WPP populations (Figure 4.2). These data suggest that the F and S populations may share a higher degree of similarity in overall patterns of gene expression early in pupariation. The dense clustering of samples within the F WPP group demonstrated the tight control of gene regulation in the fat body during this important developmental transition. However, changes in gene expression were less consistent in the S white prepupal stage.

We then quantified the trends that we observed in PCA by calculating the pair-wise Pearson product-moment correlation coefficient (r) between all 24 samples with respect to genome-wide expression profiles (Figure 4.3A). From these values we calculated the average correlation coefficient (\bar{r}) of samples within and across each major group (Figure 4.3B). Gene expression patterns within groups were highly correlated, with \bar{r} exceeding 0.90 in the F 3IN, F WPP and S 3IN groups (Figure 4.3B). However, the samples within the S WPP group were more variable, which resulted in a significantly lower \bar{r} of 0.74 ± 0.06 compared to the other within group correlations ($p < 0.05$, Figure 4.3B). One reason for the high degree of variability in the S WPP group, which was not observed in the PCA, was the poor correlation of one of the S_C biological replicates to all other samples experiment-wide (Figure 4.2, bottom row). This even included a relatively low level of correlation with the other S_C WPP biological replicate ($r = 0.76$; Figure 4.2). The poor correlation observed

between the S_C WPP replicate pair was uncommon, as r exceeded 0.92 between all other biological replicate pairs and averaged 0.96 ± 0.02 overall (Figure 4.3B).

Next, we wanted to understand how similar the gene expression patterns were between each major group. To do this we calculated the average correlation of samples across groups. Groups at different developmental timepoints had low correlation coefficients, with \bar{r} across samples of F 3IN and F WPP equal to 0.79 ± 0.02 and \bar{r} across samples of S 3IN and S WPP equal to 0.73 ± 0.3 (Figure 4.3B). These correlations were significantly lower than within group \bar{r} for either F 3IN or S 3IN respectively (\bar{r} within samples of F 3IN vs. \bar{r} across samples of F 3IN and F WPP: $p < 0.03$; \bar{r} within samples of S 3IN vs. \bar{r} across samples of S 3IN and S WPP $p < 1.1 \times 10^{-3}$; Figure 4.3B). These comparisons suggest that pupariation is sufficient to significantly alter patterns of gene expression in both the F and S populations.

We then looked for differences across the F and S populations during and after the onset of pupariation. Samples in the F 3IN group tended to be less correlated to those in the S 3IN group than they were to themselves, however the data failed to reach significance (\bar{r} within F 3IN = 0.94 ± 0.01 ; \bar{r} across F 3IN and S 3IN = 0.89 ± 0.01 ; Figure 4.3B). This further suggested that overall gene expression early in pupariation is relatively similar between the F and S populations. We also found that the samples in the F WPP group were significantly less correlated with those in the S WPP group than they were to themselves (\bar{r} within F WPP = 0.99 ± 0.001 ; \bar{r} across F WPP and S WPP = 0.80 ± 0.04 ; Figure 4.3B). These findings suggest that selection has a significant effect on the patterns of gene expression following the onset pupariation. Furthermore, the high degree of within-group variance in

the S WPP further suggests that fat body-specific gene expression may differ across the S replicate populations at the onset of metamorphosis.

The onset of pupariation results in the differential expression of many genes within the fat body.

Next we analyzed the dataset for differential gene expression, using a multi-factor design with development (3IN | WPP) and selection (F | S) as the main effects, along with a development by selection interaction term (Methods). We first screened for genes with a significant development term to analyze the overall effects of pupariation on gene expression. In total, we found 1,880 genes whose expression significantly differed between 3IN and WPP ($p < 0.05$, Benjamini-Hochberg (BH) adjusted for multiple comparisons). Out of this set of 1,880 genes, 92 also had a significant development-by-selection interaction term. These genes were removed from the list for later analysis. This resulted in a set of 1,788 genes for analysis. We found that a majority of these genes were downregulated, with 1,136 genes displaying lower expression at the WPP developmental timepoint compared to the 3IN. The degree of downregulation varied with \log_2 -fold changes ranging from -0.33 to -8.25, resulting in an average \log_2 -fold difference of -2.00 ± 0.04 . The remaining 652 genes were upregulated in response to pupariation with an average \log_2 -fold change of 1.77 ± 0.05 , which ranged from 0.29 to 9.67.

We first examined the 10 most highly up- and downregulated genes. The 10 most upregulated included several ecdysone-inducible genes, which are known to be associated with metamorphosis but may also be involved in immune responses to bacteria and autophagic cell death (*Eig71Ei*, *Eig71Eh* and *Eig71Ef*; Table 4.1). The other 7 genes have not

been previously characterized in *Drosophila*, however two are predicted to be involved in proteolysis (CG18179 and CG31954), while CG42717 is predicted to function as a serine-type endopeptidase inhibitor (Table 4.1). We observed that several of the top 10 genes encoded a conserved protein domain which is not functionally classified in *Drosophila*, but is predicted to generate a signaling peptide that is likely excreted (CG43082, *Eig71Ei*, *Eig71Eh* and *Eig71Ef*, Insect protein of unknown function; Interpro: IPR003475). This domain was also overrepresented when considering all 652 upregulated genes, and included several other ecdysone-inducible genes (*Eig71Ea*, *Eig71Eb*, *Eig71Ec*, *Eig71Ed* and *Eig71Eg*; Table 4.2). We also found enrichment for upregulation of genes involved in defense response, response to bacterium and proteolysis (Table 4.3). Next we looked for over-represented pathways and found enrichment for genes associated with the proteasome (Table 4.4). This included a core set of proteasomal genes coding for the α and β proteasomal subunits (*Pros β 2*, *Pros β 4*, *Prosa2* and *Prosa6*) as well as several regulatory particles (*Rpn1*, *Rpn9*, *Rpn10*, *Rpt1*, *Rpt3*, *Rpt4*, *Rpt5*). The core proteasomal set of genes combined with other upregulated genes, including *Pl31*, *Cul1*, *IKK β* , CG1440 and *Pomp*, to generate enrichment for pathways involved in a variety of cell signaling pathways (described in Table 4.4).

Next we examined the ten most downregulated genes in response to pupariation. Downregulated genes were associated with lipid and cholesterol homeostasis (*mag*), sterol binding and transport (*Npc2c*), proteolysis (*Jon74E*) and puparial adhesion (*Sgs1*, *Sgs3* and *Sgs4*; Table 4.1). The 4 other most downregulated genes are uncharacterized and have no predicted functions (CG31698, CG13460, CG15404 and CG14850). We then analyzed the entire set of 1,136 downregulated genes and found enrichment for single-organism

transport, system development, neurogenesis, ribosome biogenesis, hemolymph coagulation, response to starvation, protein targeting to membrane, rRNA metabolic process, protein localization to the endoplasmic reticulum and cellular response to external stimuli (Table 4.3). Some of these categories such as single-organism transport, neurogenesis and system development were fairly broad and relatively non-informative. However, genes within these categories associated with a variety of processes including sugar or ABC transport activity, phagosome formation, vesicle transport and cellular differentiation pathways (data not shown). We also found several pathways which were over-represented in the downregulated gene set. These included protein processing in the endoplasmic reticulum, ribosome biogenesis and protein export (Table 4.3). The downregulated genes were also enriched for sequences coding for several protein domains, including cytochrome P450, peptidase M13 and Immunoglobulin E-set (Table 4.2).

Starvation-selection alters the expression of genes within the fat body during pupariation.

Next, we wanted to examine differences in gene expression between the F and S populations. To do this we screened for genes with a significant selection term within our multi-factor model. In total we found 188 genes with significant differences in gene expression in response to selection ($p < 0.05$, BH adjusted). Within this set of 188 genes, we found 20 which also had a significant selection by development interaction term. These genes were filtered for later analysis. This resulted in a set of 168 genes, which were up- or downregulated in the S populations with respect to F gene expression levels. We found 77 upregulated genes with an average \log_2 -fold expression increase of 2.3 ± 0.2 (range= 0.5 to

6.4). The other 91 genes were downregulated with an average log₂-fold expression decrease of -1.8 ± 0.1 (range= -0.6 to -4.7).

We analyzed the up- and downregulated gene lists to look for over-represented gene ontology terms, pathways and protein domains, but failed to find significant enrichment. For further analysis, we decided to divide the set of 168 genes into groups based on developmental patterns of gene expression. Specifically we wanted to examine the effects of selection on gene expression for genes whose expression increased, decreased or stayed constant during pupariation. First we considered genes which did not differ in their expression between 3IN and WPP, but were significantly different between the F and S populations (see Figure 4.4 for example). There were 109 genes which met these criteria, 52 of which were upregulated in the S populations, while 57 were downregulated. Again, we failed to find significant enrichment for any gene ontology, pathway or protein domain categories. We examined the 10 most upregulated genes and found they were associated with carnitine synthesis (CG10814), cAMP-dependent protein kinase regulation (CG14692), long non-coding RNA's (CR45194, CR44077 and CR45469), phototransduction and G-protein coupled receptor signaling (*inaD*), degradation of glycans within the lysosome (*LManVI*), sensory perception of chemical stimuli (*dpr4*), glutathione S-transferase activity (*GstD2*) and proteolysis (CG31326; Table 4.5). We then examined the 10 most downregulated genes and found they were associated with stress/bacterial response induced by the humoral factor Turandot (*Victoria*, *TotC*), chitin binding (CG10725, CG10405), ecdysteroid metabolism (CG9509), ligand-gated ion channel activity (*Ir76a*), long non-coding RNA (CR43166) and uncharacterized genes with no predicted function (CG14357, CG34034; Table 4.5).

Next we returned to the list of 168 genes with a significant selection term and filtered for genes whose expression was also significantly altered by development. First we focused on genes which were significantly downregulated during pupariation, but at different levels between the F and S populations (see Figure 4.5 for example). We found 40 genes that met these criteria, with 19 upregulated and 21 downregulated in the S populations. We examined the ten most upregulated genes and found they were associated with several cytochrome P450 enzymes (*Cyp4e3*, *Cyp4ad1*, *Cyp9b1* and *Cyp28a5*), a glutathione transferase (*GstE3*), carnitine biosynthesis (CG4335), dorsal/ventral axis polarity specification and regulation of protein secretion (*sel*), synaptic vesicle exocytosis (*cpx*), proteolysis (CG10073) and an uncharacterized gene with no predicted function (CG15879; Table 4.6). We then examined the 10 most downregulated genes and found they were associated with chitin metabolism (*Muc96D*), negative regulation of pre-miRNA processing (*lin-28*), serine-type endopeptidase and hemolymph coagulation (CG11313), long non-coding RNA (CR44510), glutathione metabolism (*GstE7*), G-protein couple receptor/stress response (*mthl15*), GABA transporter (*Gat*), protein O-linked glycosylation (CG30463), ionotropic glutamate receptor (*clumsy*) and an uncharacterized gene with no predicted function (CG34291; Table 4.6).

Lastly, we examined the remaining 19 genes from the set of 168 that were differentially expressed in response to selection. Genes in this set also had a significant development term and were upregulated in response to pupariation (see Figure 4.6 for example). Within this list we found 6 genes that were upregulated in the S populations and 13 which were downregulated. The 6 upregulated genes were associated with proteolysis (CG8299), trypsin inhibition (CG31777), a tetraspanin membrane protein (*Tsp42Ed*),

glutathione peroxidase (*PHGPx*), oxidoreductase activity (CG11257) and an uncharacterized gene with no predicted function (CG42711; Table 4.7). The 10 most downregulated genes were associated with lipase activity (CG11406), peptidoglycan catabolism/stress response (*PGRP-SB1*), proteolysis (CG12133, CG30287, CG30088), small GTPase mediated signal transduction (*Rgk1*), hemolymph coagulation (CG42817), mesoderm development (*Swip-1*), proteasomal ubiquitin-dependent protein catabolism (*Ppa*) and an uncharacterized gene with no predicted function (CG42876; Table 4.7).

Many genes have complex patterns of expression that are dependent on both selection and development.

Finally we examined genes whose expression resulted in a significant selection by development interaction. In other words, the effect of selection on gene expression changed depending on the developmental timepoint. In total there were 477 genes with a significant interaction term ($p < 0.05$, adjusted for multiple comparisons). We performed a *post-hoc* analysis to investigate differential gene expression across 4 different contrasts, which included F 3IN vs. F WPP, S 3IN vs. S WPP, F 3IN vs. S 3IN and F WPP vs. S WPP. Comparing F 3IN vs. S 3IN and F WPP vs. S WPP allowed us to address the effects of selection on gene expression during and after the onset of pupariation, while comparing F 3IN vs. F WPP and S 3IN vs. S WPP helped describe how gene expression changed in response to pupariation for both the F and S populations. Ultimately this analysis allowed us to make statements such as: Expression of gene X is equal in the F and S populations prior to pupariation ($F\ 3IN = S\ 3IN$), during pupariation expression increases in the S populations ($S\ 3IN < S\ WPP$) but remains the same in the F populations ($F\ 3IN = F\ WPP$),

resulting in higher expression of gene X in the S populations at the end of pupariation (F WPP < S WPP). Analysis of the 477 genes found that they clustered into 23 different patterns, which can be determined from the data in Appendix F. The complexity of these interactions is interesting, but difficult to parse into meaningful patterns. Instead, we decided to simplify the analysis of genes with a significant interaction term, by examining gene lists across each of the 4 contrasts.

First we analyzed gene expression differences between the F and S populations during the 3IN developmental timepoint (F 3IN vs. S 3IN). In total there were 25 genes which were differentially expressed, with 4 upregulated and 21 downregulated in the S populations in comparison to the Fs. We did not find enrichment for any gene ontology terms, pathways or protein domains within these sets. We examined the genes with the highest expression and found that they were associated with proteolysis (CG5715), acetyl-CoA biosynthesis/citrate metabolism (*ATPCL*), lipid/triglyceride homeostasis and regulation of response to oxidative stress (*iPLA2-VIA*) and an uncharacterized gene with no predicted function (CG14961; Table 4.8). We then assessed the 10 most downregulated genes. The top 5 were uncharacterized proteins with no predicted function (CG5084, CG5767, CG9682, CG31516 and CG5770). The others were associated with carbohydrate metabolism (*Cda9*), chitin metabolism (CG10140 and *obst-J*), transmembrane transport (*hoe2*) and ecdysis-triggering hormone signaling (*ETHR*; Table 4.8).

Next we examined differential expression between the F 3IN and F WPP groups. In total we found that 108 of the 477 genes with a significant interaction term were differentially expressed in the F populations during and after the onset of pupariation. Out of 108 genes, 21 were upregulated in the F WPP group compared to the F 3IN group, while

97 genes were downregulated. We assessed the top 10 most highly upregulated genes and found that the gene with the largest increase in expression was uncharacterized with no predicted function (CG43133). The others were associated with transmembrane transport (CG12194), G-protein coupled acetylcholine receptor signaling (*mAChR-B*), 3-hydroxyacyl-CoA dehydrogenase activity (CG9914), protein membrane targeting (*Mctp*), MAATS domain involved in spermatogenesis (CG15145), iron ion homeostasis (*Mco1*), protein lipidation (*PIG-C*), acyl-CoA oxidase/fatty acid β -oxidation (*Acox57D-p*) and phosphatidylinositol transporter activity (*rdgB β* ; Table 4.9). We then examined the 10 most downregulated genes and found that they associated with puparial adhesion (*Sgs7*, *Sgs8*), transmembrane transport (*MFS9* and *hoe2*), larval chitin-based cuticle development (*Lcp3*), ecdysis triggering hormone signaling (*ETHR*), protease inhibitor activity (CG5767), immune response (CG15068) and uncharacterized genes with no predicted function (CG5084 and CG5767; Table 4.9). Several components of the proteasome were also upregulated, which resulted in many over-represented pathways within the gene set (*Pros β 6*, *Rpn2*, *Rpn5* and *Rpn6*; Table 4.10).

We next looked at genes with differential expression in the S populations between the 3IN and WPP developmental timepoints. 354 genes were differentially expressed, with 319 upregulated and 35 downregulated in the S WPP group compared to the S 3IN. Interestingly, 68 of the upregulated genes were found to form a network of physical interactions (Figure 4.7). In total the 68 nodes formed 18 sub-networks ranging in size from 2-12 nodes. Genes within this network were enriched for gene ontology terms associated with mitotic spindle organization, cytoskeleton organization, protein folding, microtubule-based process and single-organism organelle organization (Table 4.11). Next,

we expanded the analysis to include all 319 upregulated genes and found enrichment for pathways involved in mitochondrial translation as well as mRNA splicing and RNA degradation (Table 4.12). These pathway enrichments were largely due to the presence of 31 nuclear and mitochondrial ribosomal subunits as well as 12 genes that associated with the spliceosome. The ten most upregulated genes were associated with phosphatase activity (CG9452), a secretory protein (*Ag5r*), fatty acid metabolism (CG10131), non-coding RNAs (*MRE16* and *CR43957*), short chain dehydrogenase/oxoreductase activity (CG14946), actin filament organization (*Arpc3B*), serine-type endopeptidase activity (*l(2)34Fc*) and uncharacterized genes with no predicted function (CG9689 and CG44250; Table 4.13). We then focused on the 35 genes which were downregulated in the S WPP with respect to the S 3IN. We failed to find enrichment for any gene ontology terms, protein domains or pathways within this set. The ten most downregulated genes were associated with sodium-neurotransmitter symport activity (CG13795), alcohol dehydrogenase (*Adh*), cytochrome P450 oxidation-reduction process (*Cyp28d1*), acetyl-CoA biosynthesis and citrate metabolism (*ATPCL*), DNA methylation (*Ipod*), AMP deaminase (*AMPdeam*), body morphogenesis (*Twdlg*), heat shock protein (*Hsc70-3*) and uncharacterized genes with no predicted function (CG5773 and CG14961; Table 4.13).

Finally we analyzed genes whose expression differed between the F and S populations at the WPP developmental timepoint. This amounted to 399 genes, 357 of which were upregulated in the S relative to F populations, while 42 were found to be downregulated. Of the 357 upregulated genes, 293 were also upregulated in the previous S WPP vs. S 3IN comparison. This led to a similar protein interaction network, which included 74 nodes with network sizes ranging from 2 to 19 (Figure 4.8). These 74 genes

were enriched for similar gene ontology terms such as mitotic spindle organization, mRNA metabolic process, gene expression, microtubule-based process, organelle organization, cellular nitrogen compound metabolic process and protein folding (Table 4.14). We also found enrichment for pathways associated with mitochondrial translation elongation and termination as well as mRNA splicing (Table 4.15). The ten most upregulated genes were associated with metalloproteinase activity (CG5715), fatty acid metabolism (CG10131), phosphatase activity (CG9452), ATP hydrolysis coupled proton transport (CG31030), non-coding RNA (*MRE16*), a pseudogene (CR32207), ecdysteroid metabolic process (CG9521), sterol O-acetyltransferase activity (CG5397), odorant binding protein (*Obp99a*) and an uncharacterized gene with no predicted function (CG1552; Table 4.16). Next, we examined the 42 genes which were downregulated in the S populations with respect to the Fs at the WPP stage. This set was enriched for genes involved in catabolism (GO:0009056, 13 genes, $p < 4.5 \times 10^{-3}$). These catabolic genes were associated with the proteasome (*Rpn2*, *Rpn5*, *Rpn6*, *Prosβ6*), alcohol dehydrogenase activity (*Adh*), lipid metabolism and TG mobilization (*bmm*), ubiquitin dependent proteolysis (*Usp14*), glycolytic processes (*Ald*), glycoside catabolic process and bacterial defense (*Fuca*), transcriptional regulator of lipid biosynthesis (*SREBP*), cellular response to oxidative stress and catabolism of misfolded proteins (*Lon*), glycerol-4-phosphate metabolism (*Gdph*) and fatty acid β -oxidation (*Acox57D-p*; Table 4.17). We then examined the 10 most downregulated genes. They were associated with alcohol dehydrogenase activity (*Adh*), body morphogenesis (*TwdlG*), G-protein coupled acetylcholine receptor signaling (*mAchR-B*), transcriptional regulation of defense response to fungus (*Lmpt*), 3-hydroxyacyl-CoA dehydrogenase (CG9914), ABC-

transport like protein (CG31793), DNA methylation (*Ipod*), transmembrane transport (CG12194 and *Mctp*) and iron ion homeostasis (*Mco1*; Table 4.16).

4.5 Discussion

When populations of *D. melanogaster* are laboratory selected for starvation resistance, they adapt by delaying development to extend larval feeding time (Reynolds 2013). The extra feeding allows for greater accumulation of lipids in the larval fat body. Lipids stored within the larval fat body are carried into the adult fly where they play an important role in adult starvation resistance (Aguila et al. 2007). We are interested in understanding the mechanistic basis of the developmental delay as well as the physiology of the larval fat body in response to selection. Our preliminary data led us to hypothesize that the timing of 20E signaling was delayed in our starvation-selected populations (Reynolds 2013). If the 20E signal is simply delayed by ~24 hours in the S populations, we predicted that the transcriptomic profiles of the F and S populations should be similar during and after the late-larval 20E pulse.

To test this hypothesis we analyzed genome-wide RNA expression patterns between the F and S populations, during and after the onset of pupariation. This developmental window is known to be regulated by a late-larval pulse of the steroid hormone ecdysone which promotes differential gene expression in responding tissues. We found large-scale changes in gene expression between samples collected at the 3IN and WPP, with a total of 1,788 differentially expressed genes. This large set of genes with similar expression between the F and S populations supports our prediction and suggests that the developmental delay is due to a delay in 20E signaling. However, we also found 168 genes that were differentially expressed in response to selection and 477 with a significant selection by development interaction term. These sets of genes suggest that the S larval fat body has adapted mechanisms to alter its response to 20E signaling.

The 1,788 genes with altered expression by development were much higher than the 168 identified by selection or the 477 by the interaction between selection and development. This could suggest that development had a higher impact on gene expression than selection. However, it is important to note that the increased variability between the replicate S populations likely reduced the total number of candidates reaching significance by selection. While here we limited the analysis to the most conserved changes in gene expression across replicates, future studies can probe for differences between the replicate populations.

Many of the genes whose expression was altered by development were associated with protein metabolism. This included the upregulation for many genes involved in proteasome structure and function, as well as the downregulation of genes involved in ribosome biogenesis, protein processing and export. Results from other studies support the idea that these processes may be regulated by 20E. For example, proteasomal gene expression is 20E-inducible in other larval tissues in *Drosophila* (Li and White 2003). Furthermore, proteasome activity during metamorphosis has been associated with programmed cell death of larval tissues in *Bombyx mori* (Jia et al. 2007). Genes associated with ribosome biogenesis may also be 20E-induced, as 20E has been shown to downregulate *Myc*; a transcription factor important in ribosome biogenesis (Delanoue et al. 2010). *Myc* expression was also found to be downregulated here in response to development (\log_2 -fold change of -1.45, $p < 3.9 \times 10^{-7}$, Appendix D).

We also found enrichment for genes associated with immune response and starvation within the developmentally regulated gene set. These findings are similar to other studies of whole-body gene expression during pupariation in *Drosophila* (Barnett et

al. 1990; Beckstead et al. 2005). The up-regulation of immune-defense genes in response to 20E is hypothesized to increase protection for the pupa as it enters a compromised state during metamorphosis (Regan et al. 2013). Genes associated with starvation were downregulated in the WPP samples and primarily associated with ribosome biogenesis. However, several of these genes are also regulated by Tor signaling and associated with cell growth and division (*l(2)k09022*, CG11920, CG12301, *l(1)G0020*, *Nop60B*, *NHP2*, data not shown).

Surprisingly, development led to reduced expression of several *Sgs* genes which are typically expressed in the salivary glands (Li and White 2003). Due to their high expression and secretion from the salivary gland during pupariation, it is possible that these are artifacts derived from sample preparation. However, several *Sgs* genes have been previously identified in a screen for genes that are positively regulated by the insulin signaling pathway in the *Drosophila* fat body (L.P. Musselman, personal communication). Furthermore, 9 of the genes we identified as differentially expressed in response to selection were also identified in this insulin pathway screen (CG30463, *P58IPK*, *aralar1*, CG10814, *Cyp9b1*, *TotC*, CG15879, CG4335, *Victoria*; L.P. Musselman, personal communication). Interestingly, all of these genes except for *P58IPK* and *aralar1*, were included in the top 10 most up- or downregulated lists, and many of them do not have previously characterized function.

Overall, there were fewer genes that were differentially regulated in response to selection compared to developmental stage. This gene set was also not enriched for any pathways or Gene Ontology categories. However, by breaking the set of 168 genes into groups based on the pattern of expression during development, we were able to provide

context for how these genes may respond to 20E. For example, we found a subset of genes that were differentially expressed in response to selection, but did not change in response to development. These genes are likely not 20E-induced, and may represent the activity of other pathways that alter the physiology of the S larval fat body. Genes within this group were associated with many processes such as chitin binding, immune defense and ecdysteroid metabolism (Table 4.5). Chitin is an integral component of the extracellular matrix, and it must be properly regulated during tissue remodeling throughout development (Dong et al. 2014). 20E induces the expression of enzymes which degrade the extracellular matrix of the larval fat body (Bond et al. 2011). This process leads to the dissociation of the larval fat body into individual cells. Our preliminary observations of the S larval fat body have found that it is not fully dissociated in the adult fly upon eclosion (Personal communication, N.D. Bond). This unique physiology could be indicative of incomplete or delayed response to 20E in the S larval fat body, and is now correlated with genes involved in extracellular matrix composition. Selection was also found to decrease the expression of some genes involved in immune defense. These genes have the potential to generate niche environments for different bacterial species. This is important, because certain bacterial species have been shown to control development and metabolism in *Drosophila* (Shin et al. 2011). These genes also correlate with our preliminary studies that have found differences in the microbiome of the S populations (J. Chaston, personal communication). Finally, the differential expression of genes involved in ecdysteroid metabolism could directly affect the levels of 20E within the fat body. The gene in question, CG9509, is predicted to function as an ecdysone oxidase, which metabolizes 20E into an inactive form (Takeuchi et al. 2005). If the S larval fat body is less responsive to 20E we

might predict CG9509 would be upregulated to reduce 20E levels, however we find that it is downregulated in the S larval fat body. Interestingly, we found several cytochrome P450 genes that were downregulated during development but upregulated in the S populations (Table 4.6). While cytochrome P450 genes may have diverse functions, some are known to be involved in ecdysone metabolism (Chung et al. 2009). Understanding if and how these genes influence ecdysone or 20E metabolism in the S larval fat body, may provide further insight into its physiology during development.

The *post-hoc* analysis of genes with a significant interaction term, demonstrated some important differences between the F and S populations at the WPP stage. Specifically we found that the S populations downregulated many genes involved in catabolism, including those involved with the proteasome and upregulated many genes involved with mitochondrial translation and the spliceosome. These were particularly interesting because we had previously observed that genes associated with the proteasome and ribosome biogenesis were downregulated in response to development (Table 4.3). The downregulation of genes involved in catabolic metabolism could explain how the S larval fat body retains lipids throughout metamorphosis. This set included genes like *brummer lipase (bmm)*, which is associated with the lipid droplet and critical for TG mobilization (Grönke et al. 2005). In *Bombyx mori*, *bmm* is upregulated in the fat body during pupariation and associated with increased lipolysis (Wang et al. 2010). If catabolic genes such as *bmm* are downregulated during pupariation in the S populations, it could allow for higher retention of macromolecules in the larval fat body.

Finding the upregulation of genes associated with the spliceosome in the S populations suggests the possibility of alternative splicing. It is possible that alternative

splicing could be driving different phenotypes in the S larval fat body as lipid metabolism in the fat body has been shown to be influenced by alternative splice variants of key regulatory genes (Gingras et al. 2014). Future analysis of differentially expressed, alternatively spliced transcripts should offer more insight into these possibilities.

The examples described above are not meant to provide explanations for how the S larval fat body differs from the Fs, but demonstrate how these results may drive hypotheses to be further explored. Overall, these data suggest that gene expression in the larval fat body is differentially regulated during pupariation in response to starvation-selection. Future studies may confirm and characterize the importance of the differentially expressed genes identified here as well as look into differences between the S populations and identify alternatively spliced transcripts.

Figure 4.1. Experimental design. This diagram is an overview of the experimental design implemented in this study. Briefly, there were two laboratory selection treatments, the Fed Controls (F) and Starvation-selected (S). Each was sampled at two developmental timepoints, near the end of 3rd instar (3IN) or as a white prepupa (WPP). Each selection treatment has 3 evolutionary replicate populations (A, B and C). From each population, we sampled 2 pools of 15-25 dissected fat bodies. Each pool serves as a biological replicate. RNA was extracted from these samples and sequenced for analysis.

Figure 4.2. Principal Component Analysis of gene expression across all 24 populations. We plotted the first 2 principal components, which explain a combined ~96% of the variation in gene expression between populations. The colors represent the different selective treatments (Fed Control, F or Starvation-selected, S) at the different developmental timepoints (3IN, 3rd Instar or WPP, White prepupa). The letters “A”, “B” and “C” signify the different replicate populations from the original selection experiment. Each group has 2 biological replicates from each population, which are both simply marked “A”, “B” or “C” depending on their population of origin.

Figure 4.3. Pearson Product Moment Correlation in gene expression between groups. (A) Pairwise correlation diagram, where darker boxes signify a higher degree of correlation in gene expression between groups. (B) Average correlation of samples within and across major groups. Different letters signify significant differences between groups, $p < 0.05$, ANOVA.

CHAPTER 5

SUMMARY AND FUTURE DIRECTIONS

5.1 Overview of results and key findings

Here, I investigated the physiological and genetic basis of adaptation in populations of *Drosophila melanogaster* that were laboratory selected for starvation resistance. Previous work had found that the selected populations were obese and had reduced metabolism, poor locomotion as well as sleep and reproductive issues (Brewer, 2013; Masek et al., 2014; Reynolds, 2013). Many of these phenotypes are characteristic of metabolic disorder in mammals, which often correlates with heart disease (Poirier, 2006). I therefore hypothesized that heart function would be an evolutionary tradeoff with starvation resistance. We tested this hypothesis with the top techniques in the field. The first required a semi-intact surgical preparation followed by high-speed video microscopy and semi-optical heartbeat analysis (SOHA), and the other was an *in-vivo* imaging technique known as optical coherence tomography (OCT). Both studies found that the hearts of starvation-selected *Drosophila* were dilated and less contractile than the unselected controls, a condition known as dilated cardiomyopathy. We tested 3 competing hypotheses to investigate the mechanism of dysfunction: (1) Experimental evolution selected on alleles which directly impaired heart function; (2) selection had acted on alleles which increase lipid accumulation to levels where the excess adipose tissue physically impaired heart function; or (3) an imbalance in lipid homeostasis promoted ectopic lipid storage in the heart, leading to lipotoxicity and dysfunction. To test the first hypothesis I

performed rescue experiments where I fasted the selected populations either during larval development or as adults in order to reduce their total lipid levels to match the unselected controls. We predicted that if heart dysfunction were due to selection on alleles which directly impair the heart, then the rescue would have no effect on heart function. Alternatively if heart function improved in response to the rescue, this would suggest that there was nothing inherently wrong with the heart and dysfunction would be due to genetic factors associated with lipid homeostasis. We measured several heart parameters using SOHA and OCT and found that heart function was significantly improved in the rescued selected populations compared to their age-matched selected controls. In most cases heart function was not significantly different from the unselected controls, suggesting that there was nothing inherently wrong with the heart and that dysfunction was due to a fat-dependent mechanism. However, in some instances heart dysfunction was only partially rescued which could suggest that heart-specific alleles contribute to dysfunction. We tested the second hypothesis by performing histology and scoring for the presence of adipose tissue between the dorsal cuticle and the heart. I found that in many selected adults, the anatomical position of the heart was drastically altered and displaced away from the cuticle of the animal. The placement of the excess adipose tissue between the heart and the dorsal cuticle occurred at the attachment site of the heart tube to the dorsal cuticle through sets of alary muscles. Our observations suggest that these muscles were severely compromised, which contributed to dysfunction. Finally I explored the third hypothesis by measuring lipid content in surgically removed hearts. I found no evidence for increased lipids within the heart and further found no evidence for disrupted actin architecture which is highly correlated with ectopic lipid storage. We then hypothesized that the

selected populations had adapted by increasing the storage capacity of lipids within the fat body. I measured lipid droplets in the fat body and found that they were larger in the selected populations compared to the unselected controls. This increase was sufficient to account for the total lipid increase in the starvation-selected populations. In total these results strongly suggested that heart function is an evolutionary tradeoff to starvation resistance in the selected populations. We further found that dysfunction was highly correlated with physical interference of excess adipose tissue, although we could not completely rule out a heart-specific genetic defect contributing to the phenotype.

I next resequenced pools of genomic DNA from the selected populations and their unselected controls to explore the genetic basis of adaptation. Selection led to many genetic differences between the populations. We also found evidence for genetic heterogeneity between the selected populations, which provided the first example of non-parallel evolution in laboratory selected *D. melanogaster*. We found that the genetic differences between the replicate selected populations correlated with differences in starvation resistance. We analyzed genome-wide heterozygosity and found many signatures of selection that differed between populations and were consistent with a “hard” sweep model. These findings were also unprecedented in experimentally evolved populations of *Drosophila* and unique for selection in sexual species. Despite these interesting differences, we decided to look for consistent signals of selection across replicates. In order to discriminate between the effects of selection and genetic drift, we generated a novel algorithm to generate a distribution of allele frequencies that would be expected from genetic drift based on our experimental parameters. We applied this algorithm and found ~120,000 loci with differences in allele frequency that were consistent with selection.

These loci were mapped to a set of 1,453 genes that were involved in many processes associated with development, differentiation, growth and metabolism. We also found genes associated with many of the phenotypes that were previously measured in the selected populations. In total these findings present a unique model of adaptation and implicate many genes that may contribute to starvation resistance and its associated phenotypes.

Finally, we performed an RNA sequencing experiment on the larval fat body of the starvation-selected populations and their unselected controls during pupariation. Lipids stored in the larval fat body are an important source of fuel for adult starvation resistance in starvation-selected *Drosophila*. The larval fat body is typically remodeled during pupariation in response to the steroid hormone 20-hydroxyecdysone (20E). Initial observations suggested that 20E signaling is delayed in the selected populations. We characterized the transcriptome of the larval fat body in late 3rd instar larvae and in white prepupae in both the selected populations and the unselected controls. A large number of genes has similar patterns of expression between the selected and unselected populations. However, we found many genes with differential expression in response to selection. These findings suggest that 20E signaling in the larval fat body is altered by selection. We also found differences in gene expression patterns among the replicate selected populations. We looked for the most consistent patterns across replicates and found that the selected populations upregulated genes associated with mitochondrial translation and the spliceosome, while downregulating many catabolic genes, including those associated with the proteasome in response to pupariation. These findings provide insight into the mechanistic basis of the developmental delay in the selected populations.

5.2 Future directions

Obesity-associated heart dysfunction

The results presented here provide a detailed characterization of heart function in starvation-selected *Drosophila melanogaster*. We explored some potential mechanisms of dysfunction, but there are many follow-up experiments and improvements in techniques, which can lead to a deeper understanding of the tradeoff. For example, the rescue experiments suggested that dysfunction was largely due to fat-dependent mechanisms, however they were not able to fully falsify the hypothesis that selection acted on alleles which directly disrupt the development or function of the heart. The possibility for selection on mal-adaptive heart alleles was further supported by the genome-wide analysis, which found alleles under selection associated with 32 genes that are known to impact heart development (Appendix C, $p < 1.8 \times 10^{-6}$). Because these genes are heavily associated with developmental signaling pathways, it would be interesting to test when heart dysfunction begins in the selected populations, then explore the role of the candidate genes in dysfunction at that timepoint. Because lipid levels in the selected lines do not surpass the levels in the unselected controls until the 3rd larval instar, heart function could be tested in 1st or 2nd instar larva, 3rd instar larva and again in young adult flies. These results could help identify if the heart is disrupted during embryogenesis, when the cardiac mesoderm is specified and heart tube is formed or in response to the increased lipid levels experienced during the 3rd larval instar, or during cardiac remodeling experienced throughout metamorphosis. The results of these experiments could lead to more informed hypotheses to probe the genetic basis of dysfunction.

While we found that the increased fat body tissue between the dorsal cuticle and the heart was correlated with dysfunction, there are further experiments which could help support this hypothesis. For instance, we could perform histology in the selected populations that were rescued through fasting to see if the heart returns to its normal placement on the dorsal cuticle after total lipids are returned to control levels. Furthermore, using OCT we could measure heart function, then immediately perform histology on the same animal to see if the level of dysfunction correlates with the level of fat between the heart and dorsal cuticle. We also believe based on our observations that the alary muscles are disrupted in response to the increased fat tissue, however we have not directly tested that hypothesis here. This hypothesis could be better explored by developing techniques to either directly measure the tension provided by these muscles, or characterize the cellular architecture in these cells to see if they are compromised.

I also spent a great deal of time attempting to measure lipid levels within the heart using Coherent Anti-stoke Raman Spectroscopy (CARS). CARS is a non-labeling imaging method which has been used to measure lipid levels in several intact tissues (Chien et al., 2010). We believe this would be a much more sensitive method to measure lipotoxicity in individual fly hearts, instead of measuring lipid levels in pools of dissected hearts as performed here. Further development of this method may provide a better way to test for lipotoxicity in general and also allow to explore individual variability of lipotoxicity within the population. Our preliminary tests were limited by the permeability of the dorsal cuticle, then economical factors led to the shut down of the facility before alternate preparations could be tested.

Genome-wide analysis

The first pass through the genome-wide dataset identified several unique characteristics of adaptation for starvation selection. Finding large sweeps which were inconsistent across replicates was very different from other published studies of laboratory adaptation in *Drosophila*. We were also able to identify many genes which were closely associated with loci under selection. Despite these interesting findings, there are many follow-up experiments that would expand the scope of these findings and help better characterize the genomic basis of adaptation.

Firstly, we can explore structural variation, including insertions and deletions as well as copy number variants between populations. Natural polymorphisms of small insertions or deletions have been identified in influencing starvation resistance phenotypes (Paaby et al., 2014). Identifying these in our populations may lead to the discovery of more genes that are associated with selection. It will also help us gain a better understanding of how selection may actually be altering the function of a given gene. Copy number variants of ribosomal RNA genes have been shown to be influenced by parental diet in *Drosophila* (Aldrich and Maggert, 2015). It is possible that the starvation-selection regime could impact copy number variation, which can be explored in future analyses.

We can also examine mitochondrial polymorphisms. Several mitochondrial SNPs have been shown to influence organismal-level phenotypes, including lipid content and starvation resistance (Aw et al., 2011). In my preliminary analyses I have already identified several mitochondrial SNPs at different frequencies between the starvation-selected lines and their unselected controls. Future studies will explore the potential of these SNPs in influencing starvation-resistant phenotypes in the selected populations.

In addition to these discovery-based experiments, we can also do work to expand on the genes that were associated with selection. 542 of the 1,453 candidate genes were not previously characterized in *Drosophila*. While all of the candidates are interesting in their own right, it would be interesting to functionally investigate these genes to explore their role in starvation-selected phenotypes. Because lipid content is a relatively simple assay to perform, the candidates could be knocked down in tissues known to be important in lipid metabolism and screened for lipid content. Genes which pass the preliminary screens can be further characterized with the purpose of finding novel genes in the regulation of lipid metabolism.

Further analysis is also warranted on the genetic differences between the replicate populations. It is interesting to note that the S_A population appears to share more genetic similarity with the unselected populations in both the genome-wide analysis and the transcriptome of the larval fat body. Despite appearing more genetically similar, the S_A population was found to be the most resistant to starvation. It will be interesting to explore the genetic basis of the population-level differences and understand what genetic networks are the most efficient in conferring starvation resistance, and which are associated with functional tradeoffs.

It is also important to follow up on the drift filter and develop it into a tool that can be easily accessible for others performing E&R studies. Future work can be done to assess how the assumptions of the input parameters affect the final results. It will be important to determine how different estimates for the population size and number of generations affect the final gene lists. It would also be interesting to test our algorithm against current statistical methods and see how the results are impacted. We can also perform tests to

optimize the FDR. We used an extremely conservative FDR of 1×10^{-5} , in part because we had so many divergent loci and we wanted to narrow the search. However, in doing so we may have filtered loci that were likely under selection. This could be part of the reason for the dissimilarity between the replicate populations on the SNP level. It would be interesting to test how a lower threshold would affect the number of overlapping SNPs between replicates.

Functional genomic analysis of the larval fat body during pupariation

One interesting finding from the transcriptomic analysis of the larval fat body in the starvation-selected populations was the upregulation of genes associated with the spliceosome in response to pupariation. These findings warrant a follow-up analysis to look for differentially expressed splice variants between the populations at the different developmental timepoints. Differential splice variants of several transcription factors can lead to large changes in expression in developing tissues (Venables et al., 2012). It is possible that genes which appear to have similar expression levels in the current analysis are differentially spliced across selection treatments which could have a significant impact on the physiology of the larval fat body.

There were also many genes with unknown function that were identified as being highly up- or downregulated in response to both development and selection. Analysis of these genes affords the opportunity to discover new genes that are 20E-regulated as well as those that are altered in response to selection. To narrow the search, future studies could start with uncharacterized genes that were found to be under selection in the genomic analysis and differentially regulated in the transcriptomic analysis. These genes

could be knocked down or overexpressed in the larval fat body and screened for their effects on phenotypes such as development time, lipid accumulation or larval fat body dissociation.

Future studies may also combine the genomic and transcriptomic datasets to investigate relationships between the selected loci and changes in expression patterns. We can perform promoter analyses to test if selection has altered the binding sites for transcription factors associated with the expression of genes identified in the differential expression analysis. Because regulatory elements may exist at great distances from their actual target, we can perform the promoter analysis at different windows up- and downstream from the transcriptional start site to look for any significant associations. We can also search for over-represented sequences in the promoters of differentially expressed genes to try to find novel transcription factor binding sites.

CURRICULUM VITAE

Christopher Hardy, Ph.D.

christopher.hardy@unlv.edu
(858) 229-3658

Education

2004-2008 B.S. in Biological Sciences from the University of California, Irvine
2010-2016 Ph.D. in Biology from the University of Nevada, Las Vegas

Publications

2015 **Hardy CM, Birse RT, Wolf MJ, Yu L, Bodmer R, Gibbs AG.** Obesity-associated cardiac dysfunction in starvation-selected *Drosophila melanogaster*. *American Journal of Physiology - Regulatory, Integrative and Comparative Physiology* 309: R658–R667, 2015.
2016 (Submitted) **Hardy CM, Burke M, Han M, Everett L, Lantz K, Gibbs AG.** Genome-wide Analysis of Starvation-selected *Drosophila melanogaster*- a Genetic Model of Obesity.

Employment

2002-2005 Physics Tutor MESA Program (Mathematics Engineering Science Achievement Program for educationally underrepresented students), Santa Ana Community College
2007-2008 Physics Tutor at the UC Irvine Learning and Academic Resource Center
2008-2010 Laboratory Manager at Genescent Biotech: designed and performed experiments to find preventative medicines for aging, Huntington Beach CA.
2010-2014 Graduate Assistant, BIOL 196, BIOL 189 and BIOL 100, University of Nevada Las Vegas
2014-2016 Research Assistant, University of Nevada Las Vegas

Invited Talks

2015 56th Annual Drosophila Research Conference, Genetics Society of America, Chicago IL.
2015 Graduate College Research Reception, University of Nevada Las Vegas

Programming Languages

Python, R, UNIX-based command line tools

Honors/Awards

2006	Outstanding Team Captain, UC Irvine Rugby Organization
2007	Summer Undergraduate Research Program Fellow, University of California Irvine
2007-2008	Undergraduate Research Opportunity Program Fellow, University of California Irvine
2012	Phi Kappa Phi Chapter 100 Honors Fellow
2012	Graduate & Professional Student Association Grant Recipient, University of Nevada Las Vegas
2013	Graduate & Professional Student Association Research Forum Outstanding Presentation Award
2013	Graduate & Professional Student Association Grant Recipient, University of Nevada Las Vegas
2014	Terry Evans Scholarship Recipient
2014	Abstract-based Travel Award, American Physiological Society Intersociety Meeting: Comparative Approaches to Grand Challenges in Physiology.
2014	2 nd Place Best Poster Competition, (75 Applicants) American Physiological Society Intersociety Meeting: Comparative Approaches to Grand Challenges in Physiology
2014	3 rd Place Rebel Grad Slam Finalist, (64 Applicants). Present your thesis in 3 minutes or less to a general audience.
2015	UNLV Summer Session Scholarship
2015	Patricia Sastaunik Scholarship
2015	3 rd Place Rebel Grad Slam Finalist, (70 Applicants). Present your thesis in 3 minutes or less to a general audience.

Poster Presentations

2014	Hardy CM, Birse RT, Wolf MJ, Yu L, Bodmer R, Gibbs AG "Obesity-associated Cardiac Dysfunction in Starvation-selected <i>Drosophila melanogaster</i> " American Physiological Society Intersociety Meeting: Comparative Approaches to Grand Challenges in Physiology.
2014	Lantz K, Hardy CM, Andres A "Rab GTPases and their role in glue secretion in the larval salivary gland." 55 th Annual <i>Drosophila</i> Research Conference, Genetics Society of America.

Experience

2006-2010	University of California Irvine Science Internship: Laboratory Manager, Experiment Leader, Lab of Dr. Michael Rose
2012	Completed specialized course in RNA-Seq Bioinformatics Analysis, University of California Davis
2012-2014	President of BIOS, the School of Life Sciences Graduate Student Organization, University of Nevada Las Vegas.
2015	Student panelist at the UNLV graduate student orientation

Community Outreach

2005-2006	HOAG Hospital Clinical Care Extender Program
2011	Festival of Communities, showcased the advantages of <i>Drosophila</i> research to children (ages 5-18), University of Nevada Las Vegas
2012	Science Fair Judge for the Beal Bank USA Southern Nevada Regional Science & Engineering Fair (Elementary to High School aged participants).
2012	Hosting Calvary Chapel Christian High School students at University of Nevada Las Vegas, tour of the campus and educational outreach through discussion of personalized genetic medicine and individual DNA extraction experiment.
2013	Lectured on personalized genomic medicine and performed DNA isolation experiment with MESA (Math, Engineering and Science Achievement) student at Santa Ana Community College.
2014	“Genius Hour” Participant. Advised 4-5 th grade students on their science projects.
2014	Lectured on personalized genetic medicine and performed sheep heart dissection with Biology Club at Clark High School, Las Vegas Nevada.
2014-2015	Teaming up with the Y.O.U. organization to help elementary school students at Zel & Mary Lowman Elementary School (Las Vegas, Nevada) enter and compete in local science fairs.
2015	Hosted Clark High School students at UNLV, tour of the campus and educational outreach through discussion of personalized genetic medicine and individual DNA extraction experiment.
2015	Interviewed by Las Vegas News Channel KSNV for story discussing results from “Obesity-induced Cardiac Dysfunction in Starvation-selected <i>Drosophila melanogaster</i> ”
2014-Present	Founding member of Science Café Las Vegas, an organization dedicated to promoting scientific discussion on current events with the community.
